Economic Growth, Population Theory, and Physiology:
The Bearing of Long-Term Processes on the Making
of Economic Policy†

By ROBERT W. FOGEL*

Economic history has contributed significantly to the formulation of economic theory. Among the economists who have found history an important source for their ideas are Adam Smith, Thomas R. Malthus, Karl Marx, Alfred Marshall, John Maynard Keynes, John R. Hicks, Kenneth J. Arrow, Milton Friedman, Robert M. Solow, and Gary S. Becker. Failure to take account of history, as Simon Kuznets (1941) stressed, has often led to a misunderstanding of current economic problems by investigators who have not realized that their generalizations rested upon transient circumstances. Nowhere is the need to recognize the role of long-run dynamics more relevant than in such pressing current issues as medical care, pension policies, and development policies.

This lecture sketches a theory of the secular decline in morbidity and mortality that takes account of changes induced in physiological functioning since 1700. The synergism between technological and physiological improvements has produced a form of human evolution, biological though not genetic, rapid, culturally transmitted, and not necessarily stable, which is still ongoing in both OECD and developing countries. Thermodynamic and physiological aspects of economic growth are defined and their impact on growth rates is assessed. Implications of this theory for population forecasting, measurement of national income, demand for leisure, pension policies, and demand for health care are considered.

The attempt to explain the secular decline in mortality in a systematic way did not begin until after World War I because before that time it was uncertain whether such a decline was in progress. There were two reasons for the delay in recognizing the phenomenon. First, little was known about mortality rates before the end of the Napoleonic wars. Hardly a dozen life tables had been constructed before 1815 by various pioneers in demography, and they exhibited no clear time trend (Louis I. Dublin and Alfred J. Lotka, 1936; H. Gille, 1949). Second, there was little evidence in the first four official English life tables, covering the years 1831–1880, of a downward trend in mortality.

†This article is the lecture Robert W. Fogel delivered in Stockholm, Sweden, December 9, 1993, when he received the Alfred Nobel Memorial Prize in Economic Sciences. The article is copyright © The Nobel Foundation 1993 and is published here with the permission of the Nobel Foundation.

*Graduate School of Business, University of Chicago, 1101 East 58th Street, Chicago, IL 60637. Since this lecture is based on research still in progress, it is important to emphasize that the findings reported here are provisional and are subject to change as the current data bases expand and as the analyses of these data are refined. Nevertheless, I believe that the general outlines of the emerging new theories of mortality, morbidity, and aging are likely to survive further research. Research reported in this paper was supported by grants from the National Institutes of Health (No. PO1-AG10120-02), the National Science Foundation (No. SES-9114981), and the Walgreen Foundation. I have benefited from comments and criticisms by Christopher J. Acito, Robert M. Adams, Gary S. Becker, Christine K. Cassel, Katherine A. Chavigny, Dora L. Costa, William J. Darby, Partha Dasgupta, Sidney Davidson, Stanley L. Engerman, Phyllis Eveloth, Enid M. Fogel, Milton Friedman, Victor R. Fuchs, Zvi Griliches, Robin M. Hogarth, Susan E. Jones, John M. Kim, Peter Laslett, Lionel W. McKenzie, Reyndal Martorell, Douglass C. North, S. Jay Olshansky, Clayne L. Pope, Samuel H. Preston, Irwin Rosenberg, Roger A. Schofield, Nevin S. Scrimshaw, Robert M. Solow, Richard H. Steckel, David Sordam, Richard Suzman, James M. Tanner, Peter Temin, James Trussell, James W. Vaupel, Hans T. Waaler, Larry T. Wimmer, and E. A. Wrigley.
By the third decade of the 20th century, however, it became obvious that the new declines in British mortality rates were not just a cyclical phenomenon. Between 1871 and 1901 life expectancy in Britain increased by four years. During the next three decades there was an additional gain of 16 years. Similar declines in mortality were recorded in other European nations.

The plunge in mortality rates during the early decades of the 20th century delivered a major blow to the Malthusian theory of population. Improvements in mortality were supposed to be short-lived because, under the conditions of population pressure against the food supply that Malthus specified, the elimination of deaths due to one disease would be replaced by those due to some other malady. Efforts to reconcile Malthusian doctrine with the observed mortality decline, to modify it, or to replace it produced a large new literature.

I. Explaining the Secular Decline in Mortality

The drive to explain the secular decline in mortality pushed research in three directions. First, there was a concerted effort to develop time series of death rates that extended as far back in time as possible in order to determine just when the decline in mortality began. Second, the available data on mortality rates were analyzed in order to identify factors that might explain the decline as well as to establish patterns or "laws" that would allow predictions of the future course of mortality.

Third, a widespread effort was undertaken to determine the relationship between the food supply and mortality rates. There were several aspects to this effort. Perhaps the most important was the emergence of a science of nutrition that identified a series of diseases related to specific nutritional deficiencies and discovered the synergy between nutrition and infection (Nevin S. Scrimshaw et al., 1968). Another aspect was the emergence of the field of development economics after World War II as part of the campaign to close the yawning gap in income, health, and life expectancy between the industrialized nations and the "developing nations." Still another aspect was the combined effort of economic and demographic historians to study the role of mortality crises and their relationship to famines during the 17th and 18th centuries.

Prior to the 1960's, efforts to reconstruct the secular trend in European mortality were focused primarily on notable local communities and parishes. However, developments in statistical techniques and the remarkable reductions in computational costs during the 1960's and 1970's made it possible to draw and process large nationally representative samples. The results of these efforts, combined with official statistics after 1830 in France and after 1871 in England, are displayed in Figure 1. Analysis of the French and English series revealed that the secular decline in mortality took place in two waves. In the English case the first wave began during the second quarter of the 18th century (18-II) and lasted through 19-I after which mortality rates stabilized for half a century. The decline resumed during 19-IV and continues through the present. The French case is similar, except that the first wave of the decline in mortality began about half a century earlier in France, and its rate of decline during the first wave was more rapid.

Perhaps the most surprising aspect of Figure 1 is the implication that the elimination of crisis mortality, whether related to famines or not, accounted for less than 10 percent of the secular decline in mortality rates (Ronald Lee, 1981; E. A. Wrigley and R. S. Schofield, 1981; David R. Weir, 1982, 1989; Toni Richards, 1984; Patrick R. Galloway, 1986; Jacques Dupâquier, 1989; Fogel, 1992b). Similar results were obtained by studies of official statistics for Sweden (Tommy Bengtsson and Rolf Ohlsson, 1984, 1985; Galloway, 1987) (cf. Zvi Eckstein et al., 1984; Gunnar Fridlizius, 1984; Alfred Perrenoud, 1984, 1991). By demonstrating that famines and famine mortality are a secondary issue in the escape from the high mortality rates of the early modern era, these studies shifted attention to the neglected issue of chronic malnutrition as the
consider the impact of improved nutrition on the secular trend in health and life expectation, on labor productivity, and on economic growth. The combination of the economic and biomedical modes of analysis has been synergistic, since it has yielded analytical insights that could not have been obtained merely by relying on the techniques of one of the disciplines.

Malnutrition can be caused either by an inadequate diet or by claims on that diet (including work and disease) so great as to produce malnutrition despite a nutrient intake that in other circumstances might be deemed adequate.¹ There can be little doubt that the high disease rates prevalent during the early modern era would have caused malnutrition even with diets otherwise adequate in calories, protein, and other critical nutrients. However, recent research indicates that, for many European nations before the middle of the 19th century, the national production of food was at such low levels that the poorer classes were bound to have been malnourished under any conceivable circumstance, and that the high disease rates of the period were not merely a cause of malnutrition but undoubtedly, to a considerable degree, a consequence of exceedingly poor diets.

A. Energy Cost Accounting and Secular Trends in Body Size

As a result of the work of agricultural historians we now have estimates of British

---

¹Before proceeding with the discussion of chronic malnutrition it is necessary to clarify a terminological confusion that has misled some investigators: the distinction between the term “diet” or food intake (which represents gross nutrition) and the term “malnutrition” (which represents net nutrition, the nutrients available to sustain cellular growth). I will not dwell on this distinction here but will only emphasize that when I mean gross nutrition I will use the term “diet” and that such other terms as “malnutrition,” “undernutrition,” “net nutrition,” and “nutritional status” are meant to designate the balance between the nutrient intake (diet) and the claims on that intake. See Fogel and Floud (1994) for a further elaboration of this distinction.

Sources: Fogel (1987 table 7) for all countries except France. For France, rows 3–5 were computed from M. A. von Meerton (1989) as amended by Weir (1993), with 0.9 cm added to allow for additional growth between age 20 and maturity (Benjamin A. Gould, 1869 pp. 104–5) (cf. Gerald C. Friedman, 1982 p. 510 [footnote 14]). The entry to row 2 is derived from a linear extrapolation of Meerton’s data for 1815–1836 back to 1788, with 0.9 cm added for additional growth between age 20 and maturity. The entry in row 6 is from Fogel (1987 table 7).

Agricultural production by half-century intervals going back to 1700. These provide the basis for national food balance sheets which indicate the secular trend in British caloric consumption (J. A. Chartres, 1985; B. A. Holderness, 1989; R. C. Allen, 1994). Supplemented by household surveys of food purchases (Carole Shammas, 1984, 1990; D. J. Oddy, 1990) (cf. Fogel, 1987), these sources indicate that average daily caloric consumption in Britain circa 1790 was about 2,060 kcal per capita or about 2,700 kcal per consuming unit (equivalent adult males). For France, Jean-Claude Toutain (1971) has constructed estimates from national food balance sheets going back to the decade preceding the French Revolution. His estimates indicate that the daily per capita caloric consumption was 1,753 kcal during 1781–1790 and 1,846 kcal during 1803–1812. Converted into calories per consuming unit, these figures become 2,290 kcal and 2,410 kcal, respectively.

One implication of these estimates is that mature adults of the late 18th century must have been very small by current standards. Today the typical American male in his early thirties is about 177 cm (69.7 inches) tall and weighs about 78 kg (172 pounds) (U.S. Department of Health and Human Services [USDHHS], 1987). Such a male requires daily about 1,794 kcal for basal metabolism (the energy required to keep the body functioning while at rest) and a total of 2,279 kcal for baseline maintenance (the 1,794 kcal required for basal metabolism plus 485 kcal for digestion of food and vital hygiene) (M. H. Quenouille et al., 1951; Food and Agriculture Organization of the United Nations, United Nations University, and World Health Organization [FAO/UNU/WHO], 1985). If either the British or the French had been that large during the 18th century, virtually all of the energy produced by their food supplies would have been required for maintenance, and hardly any would have been available to sustain work. To have the energy necessary to produce the national products of these two countries circa 1700, the typical adult male must have been quite short and very light.

This inference is supported by data on stature and weight which have been collected for European nations. Table 1 provides estimates of final heights of adult males who reached maturity between 1750 and 1875. It shows that during the 18th and 19th centuries Europeans were severely stunted by modern standards (cf. line 6 of Table 1). Estimates of weights for European nations before 1860 are much more patchy. Those which are available, mostly inferen-
tial, suggest that circa 1790 the average weight of English males in their thirties was about 61 kg (134 pounds), which is about 20-percent below current levels. The corresponding figure for French males circa 1790 may have been only about 50 kg (about 110 pounds), which is about a third below current standards.

B. Size Distributions of Calories

The synergy between the economic and biomedical lines of analysis is apparent in the new insights obtained by switching from a reliance on the mean height, the mean weights, and the mean daily consumption of nutrients to the size distributions of these variables. Because of the limits of time, I focus here on the distributions of calories.2

Size distributions of caloric consumption are one of the most potent instruments in assessing the plausibility of proffered estimates of average diets. They not only bear on the implications of a given level of caloric consumption for morbidity and mortality rates, but they also indicate whether the calories available for work are consistent with the level of agricultural output and with the distribution of the labor force between agriculture and nonagriculture (Fogel, 1991; Fogel and Floud, 1994) (cf. Wrigley, 1987). Although national food balance sheets, such as those constructed by Toutain (1971) for France over the period 1781–1952, provide mean values of per capita caloric consumption, they do not produce estimates of the size distribution of calories.3

Three factors make it possible to estimate the size distributions of calories from the patchy evidence available to historians. First, studies covering a wide range of countries indicate that distributions of calories are well described by the lognormal distribution. Second, the variation in the distribution of calories (as measured by the coefficient of variation \( s/X \)) or the Gini [G] ratio is far more limited than the distribution of income. Third, when the mean of the distribution is known, the coefficient of variation (which together with the mean determines the distribution) can be estimated from information in either tail of the distribution. Fortunately, even in places and periods where little is known about ordinary people, there is a relative abundance of information about the rich. At the bottom end, it is demographic information, particularly the death rate, which rather tightly constrains the proportion of the population whose average daily consumption of calories could have been below basal metabolic rate (BMR) or baseline maintenance.

Table 2 shows the exceedingly low level of work capacity permitted by the food supply in France and England circa 1790, even after allowing for the reduced requirements for maintenance because of small stature and body mass (cf. Herman Freudenberger and Gaylord Cummins, 1976). In France the bottom 10 percent of the labor force lacked the energy for regular work, and the next 10 percent had enough energy for less than three hours of light work daily (0.52 hours of heavy work). Although the English situation was somewhat better, the bottom 3 percent of its labor force lacked the energy for any work, but the balance of the bottom 20 percent had enough energy for about 6 hours of light work (1.09 hours of heavy work) each day.

Table 2 also points up the problem with the assumption that for ancien régime populations, a daily caloric intake that averaged 2,000 kcal per capita (2,600 kcal per consuming unit) was adequate (Massimo Livi-Bacci, 1990). That average level of consumption falls between the levels experienced by the French and the English circa 1790. In populations experiencing such low levels of average consumption, the bottom 20 percent subsisted on such poor diets that they were effectively excluded from the

---

2 See the appendix to Floud and Fogel (1994) for the estimated distributions of height, weight, and the body mass index (BMI) in France circa 1790.

3 In principle it is possible to construct size distributions of calories from household consumption surveys. Inasmuch as most of these surveys during the 19th century were focused on the lower classes, in order to make use of them it is necessary to know from what centiles of either the national caloric or the national income distribution the surveyed households were drawn.
labor force, with many of them lacking the energy even for a few hours of strolling. That appears to be the principal factor explaining why beggars constituted as much as a fifth of the populations of ancien régimes (Pierre Goubert, 1973; Carlo M. Cipolla, 1980; Peter Laslett, 1984). Even the majority of those in the top 80 percent of the caloric distribution were so stunted (height below U.S. standards) and wasted (weight below U.S. standards) that they were at substantially higher risk of incurring chronic health conditions and of premature mortality (see the next section).

III. Waaler Curves and Surfaces: A New Analytical Tool

Extensive clinical and epidemiological studies over the past two decades have shown that height at given ages, weight at given ages, and weight-for-height (a body mass index, or BMI) are effective predictors of the risk of morbidity and mortality. Until recently most of the studies have focused on children under age 5, using one or more of the anthropometric indicators at these ages to assess risks of morbidity and mortality in early childhood, and it was at these ages that the relevance of anthropometric measures originally were established most firmly (Alfred Sommer and Matthew S. Lowenstein, 1975; Lincoln C. Chen et al., 1980; W. Z. Billewicz and I. A. MacGregor, 1982; Arnfried Kielmann et al., 1983; R. Martorell, 1985). During the last few years, however, a considerable body of evidence has accumulated suggesting that height at maturity is also an important predictor of the probability of dying and of developing chronic diseases at middle and late ages (M. G. Marmot et al., 1984; Hans Waaler, 1984; A. Meredith John, 1988; Dora L. Costa, 1993; John M. Kim, 1993). BMI has similar predictive properties (Peter F. Heywood, 1983; Waaler, 1984; Martorell, 1985; P. Payne, 1992; S. R. Osmani, 1992) (cf. T. N. Srinivasan, 1992).

Height and BMI measure different aspects of malnutrition and health. Height is a net rather than a gross measure of nutrition. Moreover, although changes in height during the growing years are sensitive to current levels of nutrition, mean final height reflects the accumulated past nutritional experience of individuals throughout their growing years, including the fetal period. It follows that when final heights are used to explain differences in adult mortality rates, they reveal the effect not of adult levels of
nutrition on adult mortality rates, but of nutritional levels during infancy, childhood, and adolescence on adult mortality rates. A weight-for-height index, on the other hand, reflects primarily the current nutritional status. It is also a net measure in the sense that BMI reflects the balance between current intakes and the claims on those intakes.

A. The Relationship Between Body Size and the Risk of Death at Middle and Late Ages

A number of recent studies have established the predictive power of height and BMI with respect to morbidity and mortality at later ages. The results of two of these studies are summarized in Figures 2 and 3. Part A of Figure 2 reproduces a diagram by Waaler (1984). It shows that short Norwegian men aged 40–59 at risk between 1963 and 1979 were much more likely to die than tall men. Indeed, the risk of mortality for men with heights of 165 cm (65.0 inches) was on average 71-percent greater than that of men who measure 182.5 cm (71.9 inches). Part B shows that height is also an important predictor of the relative likelihood that men aged 23–49 would be rejected from the Union Army during 1861–1865 because of chronic diseases. Despite significant differences in ethnicities, environmental circumstances, the array and severity of diseases, and time, the functional relationships between height and relative risk are strikingly similar in the two cases.

Waaler (1984) has also studied the relationship in Norway between BMI and the risk of death in a sample of 1.7 million individuals. Curves summarizing his findings are shown in Figure 3 for both men and women. Although the observed values of the BMI (kg/m²) ranged between 17 and 39, over 80 percent of the males over age 40 had BMI's within the range 21–29. Within the range 22–28, the curve is relatively flat, with the relative risk of mortality hovering close to 1.0. However, at BMI's of less than 22 and greater than 28, the risk of death rises quite sharply as the BMI moves away from its mean value. It will be noticed that

![A. Relative Mortality Risk among Norwegian Men Aged 40–59, Between 1963 and 1979](image)

![B. Relative Rejection Rates for Chronic Conditions in a Sample of 4,245 Men Aged 23–49, Examined for the Union Army](image)

**Figure 2. Comparison of the Relationship Between Body Height and Relative Risk in Two Populations**

the BMI curves are much more symmetrical than the height curves in Figure 2, which indicates that high BMI's are as risky as low ones.

Although Figures 2 and 3 are revealing, they are not sufficient to shed light on the debate over whether moderate stunting impairs health when weight-for-height is adequate, since Figure 2 is not controlled for weight and Figure 3 is only partially controlled for height (Fogel, 1987; Fogel and
Figure 3. Relationship Between BMI and Prospective Risk Among Norwegian Adults Aged 50–64 at Risk, Between 1963 and 1979

Figure 4. Isomortality Curves of Relative Risk for Height and Weight Among Norwegian Males Aged 50–64 with a Plot of the Estimated French Height and Weight at Four Dates
Floud, 1994). To get at the "small-but-healthy" issue one needs an isomortality surface that relates the risk of death to both height and weight simultaneously. Such a surface, presented in Figure 4, was fitted to Waaler's data by a procedure described elsewhere (Fogel, 1993b). Transecting the isomortality map are lines which give the locus of each BMI between 16 and 34, and a curve giving the weights that minimize risk at each height.

Figure 4 shows that, even when body weight is maintained at what Figure 3 indicates is an "ideal" level (BMI = 25), short men are at substantially greater risk of death than tall men. Thus, an adult male with a BMI of 25 who is 164 cm tall is at about 55-percent greater risk of death than a male at 183 cm who also has a BMI of 25. Figure 4 also shows that the "ideal" BMI (the BMI that minimizes the risk of death) varies with height. A BMI of 25 is "ideal" for men in the neighborhood of 176 cm, but for tall men (greater than 183 cm) the "ideal" BMI is between 22 and 24, while for short men (under 168 cm) the "ideal" BMI is about 26.

B. Using Waaler Surfaces To Explain the Secular Decline in Mortality

Superimposed on Figure 4 are rough estimates of heights and weights in France at four dates. In 1705, the per capita food supply in France was lower than in Britain, so that average body mass was probably even lower than in Britain. Circa 1705, the French probably achieved equilibrium with their food supply at an average height of about 161 cm and BMI of about 18. Over the next 270 years the food supply expanded with sufficient rapidity to permit both the height and the weight of adult males to increase. Figure 4 indicates that it was factors associated with the gain in BMI that accounted for most of the predicted reduction in the risk of mortality before 1870. After 1870, factors associated with the gain in height explain most of the predicted mortality decline. Figure 4 also implies that, while these factors jointly explain about 90 percent of the actual decline in French mortality rates over the period between circa 1785 and circa 1870, they only explain about 50 percent of the actual decline in mortality rates during the past century. Increases in body size and the factors associated with it continued to have a major impact on the gains in life expectation among persons of relatively good nutritional status, but during the last century factors other than those related to height and BMI became increasingly important.

The analysis in this section points to the misleading nature of the concept of subsistence as Malthus originally used it and as it is still widely used today. Subsistence is not located at the edge of a nutritional cliff, beyond which lies demographic disaster. The evidence outlined in the paper implies that, rather than one level of subsistence, there are numerous levels at which a population and a food supply can be in equilibrium, in the sense that they can be indefinitely sustained. However, some levels will have smaller people and higher "normal" (non-crisis) mortality than others.4

C. The Relevance of Waaler Surfaces for Predicting Trends in Chronic Diseases

Poor body builds increased vulnerability to diseases, not just contagious diseases, but chronic diseases as well. This point is implicit in Figure 2, which shows that chronic conditions were much more frequent among

4Moreover, with a given population and technology, changes in the allocation of labor between agriculture and other sectors may lead to changes in body size and mortality. In an ancien régime economy the lower the share of the labor force that is in agriculture, ceteris paribus, the lower the share of caloric production that can be devoted to baseline maintenance. The reasoning behind this statement is as follows. Assume that one worker in agriculture feeds himself plus three persons outside of agriculture. Hence, a movement of 1 percent of agricultural workers to nonagriculture would reduce the per capita availability of food to the increased nonagricultural sector by about 1.33 percent. If baseline maintenance accounts for 75 percent of caloric consumption and if per capita calories reserved for work remain constant in the nonagricultural sector, calories available for baseline maintenance in that sector would decline by about 1.8 percent (assuming that within the agricultural sector per capita production and consumption are unchanged).
short young men in the 1860's than among tall men. Figure 5 shows that the same relationship between ill health and stature exists among the males covered by the U.S. National Health Interview Surveys (NHIS) for 1985–1988. Stunting during developmental ages had a long reach and increased the likelihood that people would suffer from chronic diseases at middle and at late ages.

American males born during the second quarter of the 19th century were not only stunted by today's standards, but their BMI's at adult ages were about 15-percent lower than current U.S. levels (Fogel et al., 1993). The implication of the combined stunting and low BMI is brought out by Figure 6, which presents a Waaler surface for morbidity estimated by Kim (1993) from NHIS data for 1985–1988.

The Waaler surface for risk from chronic conditions in Figure 6 is similar to, but not identical with, the Norwegian surface for mortality (see Fig. 4). The isomorbidity curves in ill health rise more steeply than the isomortality curves as one moves away in either direction from the optimal weight curve. Furthermore, the optimal weight curve in Figure 6 usually lies about one iso-BMI curve to the right of the optimal-weight curve computed from the Norwegian mortality data. Thus, both the Norwegian mortality data and the U.S. health data indicate that for men in the neighborhood of 1.60–1.65 meters the optimal BMI is in the range of 25–27. This is above current levels recommended by FAO/WHO/UNU (1985), falling into the lower ranges of overweight in that standard.

Figure 6 also presents the coordinates in height and BMI of Union Army veterans who were age 65 or older in 1910 and of veterans (mainly of World War II) who were the same ages during 1985–1988. These coordinates predict a decline of about 35 percent in the prevalence of chronic disease among the two cohorts. About 61 percent of the predicted decline in ill health is due to factors associated with the increase in BMI, and the balance is due to factors associated with increased stature.

The decline in the prevalence of chronic diseases predicted by Figure 6 is quite close to what actually occurred. Table 3 compares the prevalence of chronic diseases among Union Army men aged 65 and over in 1910 with two surveys of veterans of the same ages in the 1980's. That table indicates that heart disease was 2.9 times as prevalent, musculoskeletal and respiratory diseases were 1.6 times as prevalent, and digestive diseases were 4.7 times as prevalent among veterans aged 65 or older in 1910 as in 1985–1988. During the 7.6 decades separating the two groups, the prevalence of heart disease among the elderly declined at a rate of 12.8 percent per decade, while musculoskeletal and respiratory diseases each declined at a rate of 5.9 percent per decade.

Young adults born between 1822 and 1845 who survived the deadly infectious diseases of childhood and adolescence were not freer of degenerative diseases than persons of the same ages today, as some have suggested, but more afflicted. At ages 35–39, hernia rates, for example, were more than three times as prevalent in the 1860's as in the 1980's. Of special note is the much higher incidence of clubfoot in the 1860's, a birth anomaly which suggests that the uterus was far less safe for those awaiting birth than it is today.

Those who also survived diseases of middle ages were more afflicted by degenerative
chronic conditions at old ages in the 1910’s than in the 1980’s. Nearly 74 percent of the elderly Union Army veterans suffered from three or more disabling chronic conditions, which is much higher than the rate among elderly veterans in 1983 (Fogel et al., 1993). It may be true that there were less genetically frail persons among those who survived to age 65 in 1910 than there are today. If so, that genetic advantage was apparently offset by a lifetime of socioeconomic and biomedical stress that left health in old age badly impaired and that sharply curtailed the life expectations of the elderly. During the 1910’s the elderly died not from the infectious diseases that killed the great majority of their cohorts at relatively young ages, but primarily from degenerative diseases which, at the two-digit level of the International Classification of Diseases, are similar to the distribution of causes of death during the 1980’s, except that deaths from neoplasms were lower and deaths from tuberculosis were higher than in the 1980’s.

The provisional findings thus suggest that chronic conditions were far more prevalent

Note: All risks are measured relative to the average risk of morbidity (calculated over all heights and weights) among NHIS 1985–1988 white males aged 45–64.

Notes: Prevailing rates of Union Army veterans are based on examinations by physicians. Those for the 1980's are based on self-reporting. Comparison of the NHIS rates with those obtained from physicians' examinations in NHANES II indicates that the use of self-reported health conditions does not introduce a significant bias into the comparison. See Fogel et al. (1993) for a more detailed discussion of possible biases and their magnitudes.

Source: Fogel et al. (1993).

\(^{a}\)Among veterans in 1983, the prevalence of all types of circulatory diseases will be underestimated because of underreporting of hemorrhoids.

\(^{b}\)The variable indicating whether the 1983 veteran ever had hemorrhoids is unreliable.

throughout the life cycle for those who reached age 65 before World War I than is suggested by the theory of the epidemiological transition. Reliance on causes-of-death information to characterize the epidemiology of the past has led to a significant misrepresentation of the distribution of health conditions among the living. It has also promoted the view that the epidemiology of chronic diseases is more separate from that of contagious diseases than now appears to be the case.

IV. Physiological Foundations for Waaler Surfaces and Curves

What is the basis for the predictive capacity of Waaler surfaces and curves? Part of the answer resides in the realm of human physiology, which concerns the functioning of the organs and the organ systems of the body. Variations in height and weight appear to be associated with variations in the chemical composition of the tissues that make up these organs, in the quality of the electrical transmission across membranes, and in the functioning of the endocrine system and other vital systems.

Research in this area is developing rapidly, and some of the new findings are yet to be confirmed. The exact mechanisms by which malnutrition and trauma in utero or early childhood are transformed into organ dysfunctions are still unclear. What is agreed upon is that the basic structures of most organs are laid down early, and it is
reasonable to infer that poorly developed organs may break down earlier than well-developed ones. The principal evidence so far is statistical, and despite agreement on certain specific dysfunctions, there is no generally accepted theory of cellular aging (cf. J. M. Tanner, 1990, 1993).

With these caveats in mind, recent research bearing on the connection between malnutrition and body size and the later onset of chronic diseases can conveniently be divided into three categories. The first category involves forms of malnutrition (including the ingestion of toxic substances) that cause permanent, promptly visible physiological damage, as is seen in the impairment of the nervous systems of fetuses due to excess consumption of alcohol or smoking by pregnant women. Alcohol, for example, induces growth retardation in fetuses and infants and causes atrial septal defect, microcephaly, and other birth anomalies which are collectively labeled Fetal Alcohol Syndrome or Fetal Alcohol Symptoms (S. L. Robbins et al., 1984). It appears that protein calorie malnutrition (PCM) in infancy and early childhood can lead to a permanent impairment of central nervous system function (Scrimshaw and J. E. Gordon, 1968; Martorell et al., 1990; A. Chavez et al., 1994) (cf. J. J. Volpe, 1987). Iodine deficiency in utero and moderate-to-severe iron deficiency during infancy also appear to cause permanent neurological damage (Betsy Lozoff et al., 1991; Scrimshaw, 1993).

Not all damage due to retarded development in utero or infancy caused by malnutrition shows up immediately. In a recent series of studies D. J. P. Barker and his colleagues (Barker et al., 1989, 1990, 1992; Barker, 1991; C. M. Law et al., 1993; D. I. W. Phillips et al., 1993; K. Phipps et al., 1993) have reported that such conditions as coronary heart disease, hypertension, stroke, diabetes, and autoimmune thyroiditis begin in utero or in infancy but do not become apparent until midadulthood or later ages. In these cases, individuals appear to be in good health and function well in the interim. However, early onset of the degenerative diseases of old age appears to be linked to inadequate cellular development early in life. Some, but not all, such cases are associated with low birth weight. Some babies are born in the normal weight range but experience below-average infant weight gains. In other instances babies are small relative to the size of their placentas, short in relation to the size of their head, or long but thin (Barker, 1993) (cf. Tanner, 1993).

Certain physiological dysfunctions incurred by persons suffering from malnutrition can, in principle, be reversed by improved dietary intake, but they often persist because the cause of the malnutrition persists. If the malnutrition persists long enough these conditions can become irreversible or fatal. This category of dysfunctions includes the degradation of tissue structure, especially in such vital organs as the lungs, the heart, and the gastrointestinal tract. In the case of the respiratory system, for example, there is not only decreased muscle mass and strength, but also impaired ventilatory drive, biochemical changes in connective tissue, and electrolyte abnormalities. Malnutrition also has been related to the atrophy of the mucosal cells of the gut, the inhibition of wound healing, increased likelihood of traumatic shock and of sepsis, impaired functioning of the endocrine system, increased tendency to edema, electrical instability that can provoke acute arrhythmias, and degenerative joint diseases (Thomas M. Saba et al., 1983; Juan Idiaquez, 1988; G. L. Hill, 1990; M. Molly McMahon and Bruce R. Bistrian, 1990; Janis S. Fisler, 1992) (cf. Kenneth G. Manton, 1993).

Also relevant is the discovery of the relationship between birth weight and the probability of perinatal death. The curves in Figure 7 are U-shaped, indicating that in each population babies significantly heavier than the optimal weight also incur high mortality risks. Moreover the optimal birth weight in the two populations with small mothers was significantly lower than that of the U.S. population, where mothers were relatively large. It appears that prior to high-technology interventions, the size of the mother's pelvis constrained the rate at which birth size (and perhaps the robustness of the vital organs of the baby) could have increased
with the improvement in intrauterine nutrition. Babies at weights which optimized survival in a relatively tall population were at elevated risks of dying in populations with relatively short mothers, due to delivery distress. There was, in other words, an intergenerational constraint on the rate at which babies could escape from the effects of malnutrition as fetal nutrition improved (cf. R. K. Chandra, 1975).

The recent physiological findings also cast new light on the first phase of the secular decline in mortality. Some investigators have called attention to changes in age-specific mortality rates that may indicate a shift in the balance between pathogens and their human hosts (Fridlizius, 1984; Perrenoud, 1984). Although the shift has been attributed to a decline in the virulence of pathogens, not enough evidence is in hand as yet to assess this possibility. However, the recent physiological research summarized in this section suggests a new pathway through which the balance between pathogens and human hosts may have turned in favor of the hosts. In addition to the improved operation of the immune system, there is the increased capacity of a vital organ to survive the attack of pathogens as a result of increased tissue resilience, including the improved operation of the nervous system. The process could have been synergistic since the improvement in the operation of the immune system might have interacted with the increased resilience of other vital organs. The last possibility is consistent with the age-specific patterns of decline in mortality rates that have so far been uncovered for the 18th century.

V. Some Implications for Current Policy

Malthus believed that malnutrition manifested itself in the exceptional—in periodic famines and in the excess mortality prevalent among the ultra-poor of his day, who lived in misery and vice. He thought that persons near the middle of the social order, the sturdy agricultural laborer or the town artisan, were generally well fed and healthy and lived normal life spans.

We now know, however, that famines accounted for less than 4 percent of the premature mortality of Malthus’s age and that the excess mortality of the ultra-poor (the bottom fifth of society) accounted for another sixth of premature mortality. About two-thirds of all premature mortality in Malthus’s time came from the part of society that Malthus viewed as productive and healthy. Yet by current standards, even persons in the top half of the income distribution in Britain during the 18th century were

---

5Such possible synergies call into question the proposition that, because an individual appears to be currently well fed, malnutrition does not affect the outcome of diseases such as influenza, smallpox, or typhoid (cf. S. R. Duncan et al., 1993). Individuals may be more likely to succumb to such infections, even if they are currently well fed, because past malnutrition, either in utero or subsequently, has degraded vital organs (cf. Scrimshaw et al., 1968).
stunted and wasted, suffered far more extensively from chronic diseases at young adult and middle ages than is true today, and died 30 years sooner than today.\(^6\)

A. Implications for Poor Countries

The Malthusian legacy is embodied in such theses as "small-but-healthy" which holds that stunted or moderately wasted individuals may not be more vulnerable to ill health and mortality than those who conform to the U.S. standard. The paucity of life-cycle data sets for developing countries caused investigators to focus only on the early years of the life span, searching for interactions between natal or infant measures of size and measures of health and work capacity later in childhood. Such studies generally picked up the effects of only exceedingly severe stunting and wasting (more than two standard deviations below average), missing the impact of more moderate size effects, many of which do not show up until later in life (David Seckler, 1980; P. V. Sukhatme, 1982; Michael Lipton, 1983) (cf. Patrick West et al., 1990).

However, the information reported in this paper indicates that childhood stunting and wasting has a long reach, predicting chronic disease rates at young-adult and later ages. The higher prevalence of disabling chronic diseases among adults in the developing nations has escaped attention because the relevant information on such conditions is not generally collected. But the long reach of childhood malnutrition in rich countries, both now and when they were much poorer than they are today, suggests that a similar interconnection also exists in developing countries.

Chronic diseases are not the only way that chronic malnutrition reduces the productivity of the labor force. When the mean amounts of calories are as low as they are in the poor nations of the world, labor-force participation rates and measures of labor productivity are bound to be low, especially when the hours of labor are adjusted for the intensity of labor (see Fogel, 1991) (cf. Partha Dasgupta, 1993). Elsewhere (Fogel, 1991), I have estimated that when the labor input is adjusted for intensity (measured by calories), improved gross nutrition accounts for roughly 30 percent of the growth of per capita income in Britain between 1790 and 1980.

B. Implications for Rich Countries

Between 1850 and 1950 U.S. life expectation at birth increased from about 40 to 68 years. Then for the next two decades further progress in longevity came to a virtual halt. During and following this interregnum, investigators who reviewed the progress in mortality over the preceding century tended toward a consensus on three propositions:

(i) The century-long decline in mortality rates was unique and could not be repeated because virtually all of the gains made through the elimination of death from contagious diseases below age 60 had been made.
(ii) Deaths, now concentrated at older ages, were due to degenerative diseases that were unrelated to the contagious diseases that they superseded. The degenerative diseases were caused by accelerated organ losses that were part of the natural process of aging.
(iii) There was an upper limit to life expectation that was genetically determined. One influential paper put that limit at 85 ± 7 years (James F. Fries, 1980) (cf. Fries, 1989).

More recent studies, responding to the renewed decline in mortality, which this time is concentrated at ages 65 and over, have uncovered evidence that militates against the notion of a genetically fixed life span or, if it is fixed, suggests that the upper limit is

\(^6\)Premature mortality is defined here as death rates higher than the 1980 death rates when standardized for the 1700 age structure (cf. Fogel, 1986, 1992b). Estimates of the overall death rate circa 1790 are from Wrigley and Schofield (1981). Estimates of the relative death rates by deciles of the caloric consumption distribution were based on the estimated average heights and BMI in these deciles and on the relative mortality risks that they imply, as indicated in Figure 4. For further details on the computations see the appendix in Fogel and Floud (1994) and table A2 in Fogel (1993b).
well above 85. James W. Vaupel's (1991a) study of Danish twins indicates that genetic factors account for only about 30 percent of the variance in age of death. His study of Swedish males who lived to age 90 indicates that the death rate at that age has declined at a rate of about 1 percent per annum since 1950, a finding that is contradictory to the rectangularization of the survivorship curve (Vaupel, 1991b) (cf. A. R. Thatcher, 1992; Vaupel and H. Lundström, 1994; V. Kannisto et al., 1994). Two recent studies of insect populations (James R. Carey et al., 1992; James W. Curtsinger et al., 1992) indicated that variation in environmental conditions had a much larger effect on the life span than genetic factors and revealed no pattern suggestive of a fixed upper limit. Collectively, these studies do not rule out genetic factors but suggest something much less rigid than the genetic programming of absolute life spans. An emerging theory combines genetic susceptibility of various organs with cumulative insults as a result of exposure to risk.

Recent studies also indicate that age-specific rates of chronic conditions above age 65 are generally falling. According to Manton et al. (1993) the rate of disability among the elderly in the United States declined by 4.7 percent between 1982 and 1989. Put on a decade basis, this rate of decline is quite similar to the long-term rates of decline between 1910 and 1985-1988 in chronic conditions among elderly veterans (Fogel et al., 1993). The finding is consistent with the growing body of evidence (reported in Sections III and IV above) indicating that chronic diseases at later ages are, to a considerable degree, the result of exposure to infectious diseases, malnutrition, and other types of biomedical and socioeconomic stress early in life. It is also consistent with the predicted decline of about 6 percent per decade in chronic diseases based on the Waaler surface in ill health displayed in Figure 6 (cf. Steven N. Blair et al., 1989; Manton et al., 1992; Manton and Beth J. Soldo, 1992).

Much current research is now focused on explaining the decline in chronic conditions. Part of the emerging explanation is a change in life styles, particularly reduced smoking, improved nutrition, and increased exercise, which appear to be involved in reducing the prevalence of coronary heart disease and respiratory diseases. Another part of the explanation is the increasing effectiveness of medical intervention. This point is strikingly demonstrated by comparing the second and last columns of the line on hernias in Table 3, above. Prior to World War II, hernias, once they occurred, were generally permanent and often exceedingly painful conditions. However, by the 1980's about three-quarters of all veterans who ever had hernias were cured of them. Similar progress over the seven decades is indicated by the line on genito-urinary conditions. Other areas where medical intervention has been highly effective include control of hypertension and reduction in the incidence of stroke, surgical removal of osteoarthritis, replacement of knee and hip joints, curing of cataracts, and chemotherapies that reduce the incidence of osteoporosis and heart disease (Manton et al., 1993).

The success in medical interventions combined with rising incomes has naturally led to a huge increase in the demand for medical services. Econometric estimates suggest a long-run income elasticity in the demand for medical services across OECD nations in the neighborhood of 1.5 and indicate that 90 percent of the variance in medical expenditures across OECD countries is explained by variations in income (William J. Moore et al., 1992). The rapidly growing level of demand, combined with the egalitarian policy of providing medical care at highly subsidized prices, has created the crisis in health-care costs that is now such a focus of public-policy debates across OECD nations, with various combinations of price and governmental rationing under consideration (The Economist, 1990; William B. Schwartz and Henry J. Aaron, 1991; Joseph P. Newhouse, 1992; George J. Schieber et al., 1993).

Whatever the eventual outcome of these policy debates, it is clear that we are in a much different world than that of Malthus. Instead of debating whether to provide food to paupers who might otherwise die, we are now debating how to distribute services that have proved successful in raising the quality
of life of the aged and in extending life expectation. And we are now struggling with entirely new ethical issues such as whether it is right to restrict medical services that extend life of a low quality (Barbara L. Wolfe, 1986; John Sterling Shuttleworth, 1990; Edmund D. Pellegrino, 1993).

Growing opportunity to improve health at young ages, to reduce the incidence of chronic diseases at late ages, and to cure or alleviate the disabilities associated with chronic diseases raises two other post-Malthusian population issues. One is the impact of improved health on population size. A recent paper by Dennis A. Ahlburg and Vaupel (1990) pointed out that if mortality rates at older ages continue to decline at 2 percent per annum, the U.S. elderly population of 2050 would be 36 million larger than forecast by the Census Bureau (cf. Samuel H. Preston, 1993). That possibility poses policy issues with respect to health-care costs (because total medical costs may rise sharply even if cure rates continue to improve) and to pension costs (because the number of persons eligible for benefits under present proposed rules and projected levels of compensation will become so large that outpayments will exceed planned reserves).

Some policymakers have sought to meet the pension problem by delaying retirement. Such schemes are based on the proposition that improved health will make it possible for more people to work past age 65. However, the recent findings on the secular improvement in health at older ages make it clear that worsening health is not the explanation for the steep decline since 1890 in labor-force participation rates of males over age 65. As Costa (1993) has reported, the U.S. decline in participation rates of the elderly over the past century is largely explained by the secular rise in income and a decline in the income elasticity of the demand for retirement. It is also related to the vast increase in the supply and the quality of leisure-time activities for the laboring classes.

In Malthus's time, and down to the opening of this century, leisure was in very short supply in the OECD countries and, as T. Veblen (1934) pointed out, it was conspicuously consumed by a small upper class. The typical person labored over 60 hours per week for wages, and many had chores at home which consumed an additional 10 or 12 hours (Kuznets, 1952; John F. Olson, 1992; Fogel, 1993a) (cf. Jeremy Atack and Fred Bateman, 1992). Aside from sleep, eating, and hygiene, such workers usually had barely two hours a day for leisure. Although opera, theater, and ballet were available, they were too expensive to be consumed ordinarily by the laboring classes.

Over the 20th century, hours of work have fallen by nearly half for typical workers. Ironically, those in the top decile of the income distribution have not shared much in this gain of leisure since the highly paid professionals and businessmen who populate the top decile work closer to the 19th-century standard of 3,200 hours per year than the current working-class standard of about 1,800 hours. There has also been a vast increase in the supply of leisure-time activities (movies, radio, television, amusement parks, participant and spectator sports, and travel) and a decline in the relative price of such activities. Many firms cater especially to the tastes of the elderly, offering reduced prices and special opportunities. As a result, the typical worker spends two-thirds as much time in leisure activities as in work and looks forward to retirement (Fogel, 1992a, 1993a).

Given the growing and income-inelastic demand for leisure that characterizes the post-Malthusian milieu of the OECD nations, it remains to be seen to what extent the demand for leisure and retirement can be throttled. Policymakers may encounter as much resistance to efforts to reduce the implicit subsidies for leisure as they have had recently in raising the taxes on work.

VI. Some Implications for the Theory and Measurement of Economic Growth

Recent findings in the biomedical area call attention to what may be called the thermodynamic and physiological factors in economic growth. Although largely neglected by theorists of both the "old" and the "new" growth economics, these factors can easily be incorporated into standard
growth models. Viewed in the human-capital context, both factors may be thought of as labor-enhancing technological changes that were brought about by developments in the agricultural, public-health, medical-services, and household sectors. They may also be thought of as adjustments for the mismeasurement of the labor input, when labor is measured only in person-hours.

I referred to the thermodynamic factor indirectly in Section V-A, when I indicated that about 30 percent of the British growth rate over the past 200 years was attributable to improvements in gross nutrition. That computation was based on the first law of thermodynamics, which holds that energy output cannot exceed energy input. Since that law applies as much to human engines as to mechanical ones, it is possible to use energy-cost-accounting techniques to estimate the increase in the energy available for work over the past two centuries. In the British case that increase had two effects. It raised the labor-force participation rate by bringing into the labor force the bottom 20 percent of consuming units in 1790 who had, on average, only enough energy for a few hours of strolling. Moreover, for those in the labor force, the intensity of work per hour has increased because the number of calories available for work increased. This change in the intensity of effort, by itself, appears to have accounted for about 20 percent of the long-term growth rate.

The contention that the British intensity of effort increased over time may seem dubious since the work day, week, and year (measured in hours) declined significantly over the past two centuries. However, the British (and other Europeans) could not have worked at the same average intensity per hour in 1790 as they do today, since that would have required a considerably larger supply of dietary energy per capita than was actually available. Increases in the intensity of labor per hour were also a factor in the American case, where food supplies were far more abundant than in Europe. Even if it is assumed that the daily number of calories available for work was the same in the United States in 1860 as today, the intensity of work per hour would have been well below today's levels, since the average number of hours worked in 1860 was about 1.75 times as great as today. During the mid-19th century, only slaves on southern gang-system plantations appear to have worked at levels of intensity per hour approaching current standards (cf. Fogel, 1991, 1993a; Fogel and Stanley L. Engerman, 1992; Olson, 1992).

The physiological factor pertains to the efficiency with which the human engine converts energy input into work output. Nutritionists, physiologists, and development economists have contributed to the extensive literature on this topic. Since some important issues are still unresolved, a firm assessment of the physiological contribution to economic growth is not yet possible. However, some aspects of the contribution can be indicated.

Changes in health, in the composition of diet, and in clothing and shelter can significantly affect the efficiency with which ingested energy is converted into work output. Reductions in the incidence of infectious diseases increase the proportion of ingested energy that is available for work, both because of savings in the energy required to mobilize the immune system and because the capacity of the gut to absorb nutrients is improved, especially as a consequence of a reduction in diarrheal diseases. Thermodynamic efficiency has also increased because of changes in the composition of the diet, including the shift from grains and other foods with high fiber content to sugar and meats. These dietary changes raised the proportion of ingested energy that can be metabolized (increased the average value of the "Atwater factors," to use the language of nutritionists). Improvements in clothing and shelter have also increased thermodynamic efficiency by reducing the amount of energy lost through radiation.

Individuals who are stunted but otherwise healthy at maturity will be at an increased

7The discussion in this paragraph draws on Dasgupta (1993) and the sources cited there.
risk of incurring chronic diseases and of dying prematurely. To evaluate the significance of changes in the rate of deterioration of the capacity to work over the life cycle, one needs to calculate the effect of changes in stature and weight on the discounted present value of the difference between earnings and maintenance over the life cycle (cf. Dasgupta, 1993). A procedure for estimating this effect is set forth in the notes, along with illustrative estimates of the key variables. The exercise indicates that the discounted revenues would have increased by about 37 percent. This last figure, combined with a guess on the effect of the shifting of Atwater factors, suggests that the average efficiency of the human

\[ P_s = E_s^2 \left( 1 - e^{-(r + \phi + \sigma) t} \right) \]

where \( \mu \) is the rate of decline in the survivorship function (the \( l_c \) curve of the life table), \( \phi \) is the rate of decline in annual net earnings after age \( x \), \( r \) is the discount rate (which, for convenience, is set at 6 percent), \( x \) is the age at which earnings peak, \( E_s \) is net earnings at that age, \( n \) is the average number of years that elapsed between \( x \) and the average age at which a living male ceased to be in the labor force regularly (which, for convenience, will be taken to be equal to 35), and \( P_s \) is the discounted present value of the net earnings stream.

The value of \( \mu \) for 1790 was computed from Wrigley and Schofield (1981), taking the average of their \( e_0 \) for 1786–1795 (which is 36.63) and interpolating between levels 8 and 9 in their family of English life tables to obtain the proper \( l_c \) curve for circa 1790. The value of \( \mu \) over ages 35–70 in that schedule is 0.0289.

The projected shift in the \( l_c \) curve was based on the Waaler surface in table A1 in Fogel (1993b). Using 1.68 m and 61 kg for 1790, and 1.76 m and 76 kg for 1980, yields a predicted decline of 31 percent in the mortality rate. The corresponding \( l_c \) schedule was obtained from Princeton–model North tables at male level 14, using 0.69(3.5/3.9X 10) as the basis for the fit. The value of \( \mu \) between ages 35–70 in that \( l_c \) schedule is −0.0202.

The changes in \( E_s \) associated with changes in height and weight were estimated from an equation reported by Robert A. Margo and Richard H. Steckel (1982). The data they used pertained to slaves seized as booty of war by the Union Army in 1863. The traders who related the value of slaves to their height and weight appear to have focused only on the differences in the location (not the slope) of the age–earnings profile, showing no apparent awareness of the relationship of stature and BMI to mortality and chronic diseases (cf. Fogel, 1992c). The Margo–Steckel equation is:

\[ V = 2.73 + 0.032S + 0.17A - 0.005A^2 \]

\[ + 0.000046A^3 + 0.053H \]

\[ + 0.019W - 0.00027(H \times W) \]

\( N = 523, \bar{R}^2 = 0.20 \), where \( V \) is the value of a slave, \( S \) is a dummy for skin color, \( A \) is age, \( H \) is height (in inches), and \( W \) is weight (in pounds); \( t \) statistics are in parentheses. For 1790, I used 66.1 inches and 134 pounds; for 1980, I used 69.3 inches and 167 pounds. These figures indicate that \( E_s \) increased by about 7 percent as a result of changes associated with body size.

The value of \( \phi \) for 1790 between ages 35 and 70 was computed from data reported in Fogel and Engerman (1974). These data indicate that net earnings at age 70 were about 17 percent of peak earnings, which was attained at age 35.

With the foregoing information and an initial assumption that \( \phi \) remained constant, the increase in \( P_s \) can be computed from the data shown in equations (3) and (4):

\[ P_{s,1790} = \frac{E_s[1 - e^{-(0.0289 + 0.0494 + 0.0635)}}{0.1383} = 7.17E_s \]

\[ P_{s,p} = \frac{1.07E_s[1 - e^{-(0.0202 + 0.0494 + 0.0635)}}{0.1296} = 8.17E_s \]

where \( P_{s,1790} \) is the present value of the 1790 earnings profile and \( P_{s,p} \) is the present value of the profile projected from the changes in height and BMI. Equations (3) and (4) imply that \( P_s \) increased by 14 percent \((8.17/7.17) - 1 = 0.14\).

It is now necessary to take account of the effect of changes in body size on the rate of decline in the net earnings function (the value of \( \phi \)). If it is assumed that net earnings at age 70 rose from 17 percent to 40 percent of peak-age earnings as a result of physiological improvements, \( P_s \) increases by 37 percent. However, even the last figure is probably too low since it does not take account of the secular shift in the peak of the age–earnings profile from the mid-thirties to the mid-forties. Moreover, studies of the profiles of manual workers in recent times suggest that net earnings now decline much more slowly after the peak than in past times (cf. Fogel and Engerman, 1974; Mary Jablonski, et al., 1988; Kevin Murphy and Finis Welch, 1990).
engine in Britain increased by about 53 percent between 1790 and 1980. The combined effort of the increase in dietary energy available for work, and of the increased human efficiency in transforming dietary energy into work output, appears to account for about 50 percent of the British economic growth since 1790.  

Focusing on the thermodynamic and physiological aspects of economic growth calls attention to the long lags that frequently occur between the time that certain investments are made and the time that their benefits occur. Much of the gain in thermodynamic efficiency that occurred in Britain and other OECD countries between 1910 and 1980 was due to a series of investments made as much as a century earlier. Failure to take account of these extremely long lags between investments and payoffs leads to puzzling paradoxes. During the Depression decade of the 1930's, for example, the U.S. unemployment rate was never less than 16 percent; for half the period unemployment ranged between 20 percent and 25 percent. Yet life expectation between 1929 and 1939 increased by four years, and the heights of men reaching maturity during this period increased by 1.6 cm (Bernard D. Karpinos, 1958; U.S. Bureau of the Census, 1975).

The resolution of the paradox turns, I believe, on the huge social investments made between 1870 and 1930, whose payoffs were not counted as part of national income during the 1920's and 1930's even though they produced a large stream of benefits during these decades. I refer, of course, to the social investment in biomedical research (which included the establishment and expansion of modern teaching and research hospitals) whose largest payoffs came well after the investment was made. Also included in this category are such public-health investments as the construction of facilities to improve the supply of water, the cleaning up of the milk supply, the draining of swamps, the development of effective systems of quarantines, and the cleaning up of the slums.

VII. Concluding Comment

Keynes said, "In the long run we are all dead" (1971 p. 65). That was an appropriate point to make during the interwar period, which included the severe inflations of the 1920's and the worst depression in history during the 1930's. Urgent, forceful action was needed to regain control of the money supply, to take care of the millions of unemployed, and to prevent the collapse of the democracies.

We live in another era. The major issues of economic policy in OECD nations today cannot be understood from a purely short-run perspective. The crisis in medical care, the pension crisis, and the challenges of globalization are governed by long-run processes that policymakers need to understand. As I have tried to point out in this lecture, we have not yet completed the escape from hunger and premature death that began nearly three centuries ago. Chronic diseases and death are still occurring prematurely even in the rich countries. If the reforms of health care and pension programs now being considered by policymakers are to be successful, they must be con-
sistent with the long-term physiological changes governing the decline in chronic diseases and the increase in longevity. Long-term forecasts that do not take account of the dynamics of these changes over the past century, and of the socioeconomic, biomedical, and other environmental improvements that made them possible, are liable to be far off the mark.

At the outset of this lecture I stressed the need for economists to take account of long-run dynamic processes through a study of history. Uncovering what actually happened in the past requires an enormous investment in time and effort. Fortunately for theorists, that burden is borne primarily by economic historians. Theorists only need to spend the time necessary to comprehend what the historians have discovered. A superficial knowledge of the work of economic historians is at least as dangerous as a superficial knowledge of theory.
