# Agent-Based Modeling of Non-Walrasian Markets with Entrance and Exit of Agents* 

Evan J.D. Gee<br>Williams College<br>Williamstown, MA 01267

#### Abstract

Housing is a widely-studied but ultimately poorly-understood sector of the national economy. In particular, the process by which prices are created and the market-outcome is determined is of interest, but very difficult to model mathematically. Previous work has focused on attempting to analytically determine what assumptions are strictly necessary to achieve a competitive equilibrium, but has required perfect information even in the cases where the agents themselves are only boundedly rational.

In this paper I use agent-based modeling to explore not only the effects of bounded rationality, but also the effects of asymmetric information on markets. I find that even small departures from perfect information cause large changes in both the total surplus and the distribution of that surplus. Furthermore, the magnitude of these effects suggests that very few actual markets are likely to have outcomes anywhere near the competitive equilibrium.

## Introduction

Housing markets represent an interesting area of study for economists. Housing represents an important sector of the national economy, there is data available to test hypotheses, and even more appealingly, many of the phenomena associated with housing markets are still poorly understood. Finally, housing markets also have a strong parallel with another area of great interest: labor markets.

In either a housing market or a labor market, conditions very often give one side a great deal more market experience than the other, leading to information asymmetries. This dimension of housing and labor markets has not been fully integrated into the literature because of the difficulty of mathematically modeling such information states and their impacts. This is unfortunate because the implications of information asymmetry in terms of the total quantity and distribution of economic surplus can be quite significant.

In a much-cited book Strategic Foundations of General Equilibrium, Douglas Gale [4] addresses analytically the issues of what assumptions need to be made in order for a market with boundedly rational agents to reach equilibrium. My model very naturally satisfies most of these prerequisite assumptions while relaxing a couple of other key ones, allowing us to very directly test the robustness of his analytical results. While testing the sensitivity of Gale's results to changes in every assumption is not within the scope of what I hope to accomplish, I can hope to provide some insight into how actual markets might compare to these predictions.

As a practical example of the kind of market that I will be exploring, imagine a college
town filled with students looking for housing and landlords willing to provide it. Over a number of years, if no new participants enter the market and none of the current participants leave, one might imagine that the market would eventually approximate a Walrasian equilibrium as everyone eventually gains perfect information about the market. This is an unrealistic scenario, however, as very few college students rent housing for more than a couple of years, while landlords may well be in the market for many times that. Rather, new and relatively naive students come in every year while other, more 'experienced,' students graduate. If new students have approximately the same distribution of reservation prices as outgoing students, then the Walrasian equilibrium price and quantity are not affected by this churning in the market. In a non-Walrasian environment, however, changes in the relative amount of information each participant has can be quite significant; here, landlords would gain relatively high levels of knowledge compared to the students who likely only have vague secondhand anecdotes.

A solution to the difficulty of analytically modeling housing markets with asymmetric information is to use agent-based computing, a method of inquiry that allows us to relax assumptions about perfect information by modeling markets from the point of view of each individual agent. This paper makes use of such a simulation to investigate the effects of information asymmetries in a market where agents gain experience over time and change their strategies accordingly.

Section 1 reviews the idea of Walrasian and non-Walrasian markets, the literature on agent-based systems, and the game-theoretical predictions of the impact of information disparities. Section 2 sets out my model in terms of such a game, and Section 3 discusses the
outcome of various kinds of models as I vary the degree of asymmetry. Finally, Section 4 discusses the theoretical implications of this work.

## 1 Review of the Literature

### 1.1 Walrasian and Non-Walrasian Markets

The structure of a so-called Walrasian market, developed by Leon Walras, relies upon an auctioneer to act as the intermediary between buyers and sellers. The auctioneer calls out a price, and buyers and sellers are allowed to make contracts at that price. If there are more buyers than sellers willing to trade at that price (or vice-versa), all of the contracts are voided and the participants are allowed to costlessly re-contract at the next price the auctioneer chooses. Another equivalent formulation of this process is that of the profit-maximizing middleman. In typical analyses of competitive markets, the price reached by either of these processes is assumed to be the equilibrium price. In this market, then, neither renters unwilling to pay at least this price nor landlords unwilling to sell for only this price get to trade. For a market with eleven renters and eleven landlords whose reservation prices range from one to eleven at each integer, the Walrasian Equilibrium price would be six with a total of six trades. ${ }^{1}$

Many markets of interest, however, do not have a mechanism that ensures that all transactions occur at a single, market-clearing price. In particular, the markets I will be looking at replace the auctioneer with a random matching and bargaining mechanism. In such a

[^1]market, depending on the bargaining model, agents who would not get to trade in a Walrasian market may well get to trade some or even most of the time. Trades involving these agents are called 'extramarginal trades' because they involve an agent whose marginal cost is greater than the market price or whose marginal valuation is lower than the market price. One effect of these extramarginal trades is to lower the total amount of surplus received in the market; in the case with eleven renters and eleven landlords described above, for example, allowing landlord seven and renter five to trade as well results in a $6.6 \%$ drop in total surplus from 30 to 28.

### 1.2 Agent-Based Modeling

Agent-based computing has been defined as "the computational study of economics modeled as evolving systems of autonomous interacting agents" [8]. This approach is not a new one, but is rapidly gaining popularity in any number of different fields of study (including economics). Gilbert and Terna [5] argue that this approach is fundamentally different from other traditional means of investigation, or rather that it represents a third way of conducting analysis apart from verbal argumentation or mathematics.

Robert Axtell [2] points to four distinct advantages associated with approaching problems in this manner. First, this approach makes it easy to limit agent rationality. Second, even if one did wish to use perfectly rational agents, doing so would not be difficult. Third, because of the way in which this kind of simulation works, one can study not only the end state(s) of a market, but also every step along the way. Fourth, traditional mathematics has difficulty modeling either space or social networks-ideas often integral to the way in which we perceive
the world to work.
These advantages are not all equally relevant to my model, but they do suggest why a variety of disciplines have come to embrace agent-based computing as a way to solve complex problems. Of them, the first and the third are likely the most important to this particular inquiry. The first is important because one of the most difficult rationality assumptions to relax is that of perfect information; the third is relevant because I am interested not only in the final state of the market, but also in the process by which the market approaches it and the length of time it takes to do so. As Gale [4] points out, it seems self-defeating to use a method of analysis that considers only equlibria when attempting to model limited rationality, because there is no guarantee that even one such equilibrium exists.

Axtell [2] lists a single disadvantage to the agent-based method of analysis: the very nature of simulating market conditions in order to see the outcome means that a single run through the market provides very little statistically significant information. It is becoming increasingly easier to compensate for this, however, by using the ever-expanding speed of computers to run such an experiment over and over in order to calculate what outcomes can be expected.

### 1.3 Game Theory

The simulation presented in this paper aims to explore much the same kind of questions as Gale does in his book Strategic Foundations of General Equilibrium [4]. At the heart of the issue is the question of where prices come from. In 1874 Leon Walras developed a pricedetermination process in markets that requires an 'auctioneer' to set and reset prices until
the competitive outcome is achieved. As an approximation of markets in which each agent has perfect information, this kind of model continues to serve us relatively well, despite the fact that very few markets actually have someone to explicitly or implicitly play the role of auctioneer. In most markets, however, it is participants' relative knowledge about the market and their experiences that leads to prices, but developing an analytical model that uses this mechanism and therefore has the power to explain markets without perfect information has proven to be very difficult.

I, like Gale, am engaged in trying to understand the processes that generate prices and market outcomes. Gale's approach is to find a minimal set of assumptions that allows a market to reach a competitive equilibrium as time extends out to infinity. The first model Gale presents is comprised purely of a large but finite set of consumers who are randomly paired in a Dynamic Matching and Bargaining Game. Here, he finds it necessary to introduce several assumptions, including anonymity, Markov strategies, and continuity, in order to make progress. ${ }^{2}$ His second model tries to justify these assumptions in terms of bounded rationality and simplicity, and it succeeds in simplifying the analysis quite a bit. Nevertheless, both assume a possibly unreasonable knowledge about equilibrium strategies. In his third model, Gale introduces a process of random searching for a better strategy rather than relying on agents to simply intuit it. Here, it is also possible to find a competitive equilibrium, but, in order to make the analysis mathematically tractable, he moves back to a Walrasian-style auctioneer to guarantee the greatest possible surplus contingent on the agents' chosen strategies.

[^2]I, on the other hand, want to consider not only Walrasian markets, but also those in which the outcome either systematically deviates from or does not agree at all with what a Walrasian auctioneer produces. The agent-based simulation approach allows us to study not only the final state of the market but the entirety of the market progress toward whatever result develops.

## 2 Description of the Model

What follows is a description of the simulation model. In the introduction I very briefly described an example relating to a college town, an example that is a good real-world example of the model I am about to present. College towns have a relatively constant number of students looking for off-campus lodging and a number of landlords with units dedicated to pretty much just that. The market opens every spring when students have to begin thinking about the next year, and closes every fall when college actually starts. In between, students wander about looking at housing, but the order in which they encounter landlords is essentially random. Finally, while students may say for a couple of years, they are likely, on average, to be in the market for fewer years than the landlords.

### 2.1 Agents

There are two distinct types of agents: renters and landlords. Each class of agents is heterogeneous and each individual agent is fully characterizable by reservation price, defined as the price at which an agent receives no surplus from an exchange. No restriction is made on
the number of agents of each type in the market, and any number of each can be created at any reservation price. Each agent wishes to make at most one exchange, and will refuse an exchange if it does not result in at least as much surplus as the agent has come to expect in the market if he/she rejects the exchange. Each agent maximizes over a one period horizon. All agents have utility functions into which housing enters linearly.

### 2.2 Commodities

There are only two commodities in this market: housing and money. All housing units are identical and I assume, for simplicity's sake, that the difference in reservation prices for landlords is directly tied to differences in their costs of keeping their housing in the residential market.

### 2.3 Time

In order to narrow the scope of this investigation, I assume that there are no costs associated with searching for a trade. As this is the case, and because a market does not close until there are no possible trades left, I mark the passage of time within a market simulation solely by counting the number of transactions that have already occurred. This number, called the 'transaction count,' is known to all agents, and agents' expectations regarding the surplus they can expect to obtain if they reject a feasible trade are conditioned on the transaction count at which that feasible bargain occurs.

Two other ideas are important in terms of the passage of time. First, agents do not update their expectations in between every market simulation, but rather do so only at the conclusion
of some pre-defined number of market simulations. This is necessary because it is virtually certain that at least some individual market simulations will result in improbable outcomes that, if used as the sole basis for updating information, would cause very erratic swings in agents' behaviors. In my modeling this period is called a 'stage' and typically consists of 30,000 market simulations. Each of these market simulations with constant expectations is called an 'iteration'.

### 2.4 Market Interactions

Renters and landlords are placed into separate pools, and pairs are drawn at random. If a trade can be negotiated between the chosen agents, it is made and the agents are removed from their respective pools, and the specifics of the trade are recorded. Otherwise, agents are put back in their respective pools, from which they may or may not be drawn again for a bargaining encounter. A market ends if all possible trades have been exhausted, or if there have been a predetermined number of successive bargaining encounters without a successful trade. There is no possibility of 'reserving' a bargain while an agent continues to search. As it is, the particular order of the random encounters between renters and landlords can have a large effect upon the outcome of a market.

### 2.5 Information

Agents acquire information for themselves through direct experience in the market. Each agent keeps track of the amount of surplus he/she expects to receive at every transaction count from beginning to end, which is to say that in a market with eleven agents on each
side (hence eleven possible trades), each agent keeps eleven different expectations. Agents keep track of the points in the market at which they reject trades, and at the end of each stage (typically comprises 30,000 simulations), they compute the average amount of surplus they actually received at the various transaction counts in the market and they update their expectations accordingly.

Intuitively, one expects that everyone entering a housing market would have at least some sort of knowledge or expectations about the way in which that market works. In order to give agents some degree of knowledge about the market they are entering, the first stage of every simulation is a 'bootstrap' stage in which half of the trades that otherwise would have happened are randomly rejected allowing them to learn how much surplus they can expect if they reject a feasible bargain at any point. Over several thousand runs through the market, this provides a solid base of information for the agents, though it remains far short of perfect information. ${ }^{3}$

Agents' expectations for surplus, also known as disagreement-points, reflect the information that they have about the market. As agents' expectations rise, fewer and fewer trades are possible, which means that there are fewer and fewer ways for the market to play out. It is entirely feasible, for instance, to have an outcome identical to the Walrasian equilibrium in a market with entirely uninformed renters, but such an outcome would only occur by chance. The only guarantee that a market will have the Walrasian outcome is for the expectations of all renters (landlords) to be such that they insist on paying no more (receiving no less) than

[^3]the Walrasian equilibrium price. Indeed, if when I simulate a basic version of this model (see section 3.1), expectations do rise enough to rule out many possible trades, cutting down the number of outcomes. They do not, however, rise enough to bring about the Walrasian equilibrium.

For most agents expectations for the surplus they will receive if they refuse a feasible bargain declines as the transaction count rises. This makes intuitive sense, because both renters with very high reservation prices and landlords with very low reservation prices (the people with whom it is most attractive to trade) are able to make deals with a greater number of other agents and are therefore likely to exit the market earlier. Interestingly, for those agents who only rarely get to trade, however, expectations initially fall but then take a large jump as the transaction count rises high enough to indicate that the market should already have closed; even knowledgeable agents are inexperienced at high transaction counts, and at least one now-desperate low (high) reservation price landlord (renter) must remain, as at least one more trade is still possible.

### 2.6 Negotiations

When agents are randomly matched and a trade is possible given their reservation prices, I set the exchange price to be equal to that which would occur if the agents were to engage in a bargaining process based on a Rubinstein alternating-offers game to determine a price for the rental unit [6]. ${ }^{4}$ A great deal of this bargaining happens when buying or selling a housing unit, but this bargaining approach might at first seem inappropriate for rental

[^4]housing markets where, more often than not, the rental rate is set in advance by the landlord. There are, however, a few reasons why such a bargaining model is not unreasonable. First, many housing units may be rented through less formal listing mechanisms in which explicit bargaining over the rental rate is common, or by landlords who are willing to haggle. Second, even in the case of rental units in larger multi-unit buildings, some elements of bargaining do come in as renters and landlords bargain over the initial duration of the rental agreement, over the nature of improvements/repairs that the landlord will make prior to occupation, over the terms of subsequent extensions to the initial lease, and over subsequent improvements and the rent increases that should attach to them.

The Nash bargaining solution is the unique subgame perfect equilibrium for a Rubinstein alternating-offers game in this context. Each agent has not only a reservation price (as described above) but also a set of expectations about future opportunities. These expectations determine the agent's disagreement point. If a trade is possible given both agents. reservation prices and disagreement points, the trade price is such that each agent gains the same amount relative to his/her respective disagreement point. Thus,

$$
\begin{equation*}
P_{i, j}=\frac{\left(P_{R_{i}}-R E B_{i}+P_{L_{j}}+L E B_{j}\right)}{2} \tag{1}
\end{equation*}
$$

where
$\mathrm{P}_{i, j}=$ the price obtained in an exchange between renter i and landlord $\mathrm{j} ;$
$\mathrm{P}_{R_{t}}=$ the reservation price of the ith renter;
$\mathrm{REB}_{i}=$ the ith renter's expected gain if the current bargain is rejected;
$\mathrm{P}_{L_{j}}=$ the reservation price ( $=$ marginal cost $)$ of the jth landlord;
$\mathrm{LEB}_{j}=$ the $j$ th landlord's expected gain if the current bargain is rejected.

This bargaining model is fairly standard; the challenge is in finding a reasonable approach for determining the agents' respective disagreement points. The appropriate disagreement point for each agent is the amount of surplus (s)he would expect to receive if (s)he rejected the current bargaining opportunity. In a scenario with perfect information and perfectly rational behavior, such expected surplus would be a function of the numbers and reservation prices of all opposite-type and same-type agents remaining in the market, of the nature of the bargaining process that determines prices in bargaining encounters, and of the possibilities for strategic bargaining strategies. However, attempting to take all of these factors into account is analytically intractable and computationally impractical. Furthermore, it requires us to assume that agents have both exceptional analytical abilities and perfect informationassumptions I explicitly want to avoid. I therefore use experience from previous stages to set expectations for the current stage, and begin with a special 'bootstrap' stage designed to give agents initial information about what they can expect from this market.

In the first stage of every simulation, agents acquire knowledge that they can then employ in their bargaining in every subsequent stage. This information continues to evolve as the agents gain experience in subsequent stages. Ideally, the amount of knowledge gained during the bootstrap stage should be close to the amount available to traders in actual housing markets, rather than unreasonably extensive or limited. The challenge, therefore, is to give agents enough simulated information so that they have reasonable guidance while still allowing for trades at prices other than the Walrasian market clearing price.

My objective-to study what happens to markets as renters are replaced with more naive counterparts-would be compromised if the information available to renters as they entered the market were near-perfect. I have chosen to assume that during bargaining, both renters and landlords know two things: how many transactions have already occurred (the transaction count) and how much surplus an agent of his/her type (renter/landlord) and reservation price can expect to receive in the market if he/she rejects a feasible bargain at that particular transaction count. This is very much like those markets that seasonally close, such as summer rental properties or college housing, and therefore seems quite reasonable. ${ }^{5}$

The bootstrap stage is intended to give agents experience about the surplus they can expect to receive if they reject a possible trade at any given transaction count. But in the bootstrap stage itself, agents have no prior experience that could inform their judgment of possible trades. By assumption, I give them disagreement points of zero in the bootstrap stage, implying that they would accept any trade that gave them positive surplus. In effect, I assume that each agent begins this learning process with the naive belief that the alternative to accepting a feasible bargain is to receive no surplus at all. Of course, under this assumption, agents would never acquire experience about rejecting feasible trades because none of them would ever reject such a trade in the first place. A solution to this is to provide this experience for the agents by randomly selecting some of their proposed trades and canceling them, returning both agents to their respective pools. Each agent whose trade opportunity is canceled in this way records the transaction count at which it occurred as well as the

[^5]level of surplus eventually attained in that market run. These data are averaged over the 30,000 iterations of the bootstrap stage to arrive at each agent's expectations regarding the amount of surplus they can expect to receive if he/she rejects a feasible trade at any given transaction count. While these trades could be rejected with any probability greater than zero and less than one, I chose to reject them with probability one-half. ${ }^{6}$

This knowledge informs the agents' respective disagreement points in every stage after the first. It is worth noting that the amount of information agents have is constrained not only by the limits to their experience, but also by the evolving nature of the market. Information gathered in the previous stage cannot fully inform the present stage because agents update their information (and hence their strategies) between stages. Even with perfect information from the previous stage, agents may well not use an optimal strategy because of the changes in others' expectations. Of course, once in equilibrium, agents' strategies cease to change because their experiences simply reinforce their previous strategy: any deviation is punished either by leaving the agent without a trade (if expectations are excessive) or with less surplus than (s)he could have gotten (if expectations are too low). Note that bounded rationality-a result of market evolution-does not necessarily rule out an equilibrium, because changes in strategy slow down as the market moves closer.

Agents with different reservation prices will naturally have different experiences. Furthermore, an agent's expected surplus after rejecting a feasible trade will vary with the transaction count. At any given point in the market, agents who are more favorably situated (renters with high reservation prices and landlords with low reservation prices) are more

[^6] to either one quarter or three quarters has no effect.
likely to be matched with an opposite type agent with whom a bargain is feasible than are less favorably situated agents. ${ }^{7}$ Their expected surplus conditional on rejecting a feasible trade at that transaction count will thus be higher. At the same time, because these more favorably situated agents are withdrawn from the pools from which agents are selected in the matching process when they complete a bargain, the pools of renters and landlords from which agents are drawn becomes increasingly dominated by low reservation price renters and high reservation price landlords over the course of a market run. The result is that for the typical agent, the expected surplus received after rejecting a feasible bargain falls as the transaction count increases. Thus the agents' disagreement points in their bargaining encounters, which are derived from experience in previous stages, will vary both as a function of their reservation prices and the transaction count.

This system of using previous experience as well as a specially tailored first stage creates disagreement points for agents in their bargaining throughout the entirety of the simulation. Any trade from which both agents would gain surplus at least equal to his/her expectations for surplus (at that transaction count) will take place, and the market proceeds until no further trades are possible. Again, in order to make sure that the data are representative of all of the possible outcomes (as well as their relative probabilities), each stage is run for 30,000 iterations.
${ }^{7}$ This advantage disappears as the market begins to converge toward equilibrium as favorably situated agents increase their expectations and thereby rule out some agents of the opposite type.

### 2.7 Information Asymmetry

The focus of my work is to investigate how market outcomes-output, total surplus, and its distribution between renters and landlords-are affected by the exit and entry of renters. In order to simulate such a flow of old renters out of the market and new renters into the market, at the end of each stage a number of renters are selected at random and are replaced with new agents of identical type and reservation price but equipped with only the knowledge an identical agent had at the end of the bootstrap stage. Because each agent consists only of a reservation price, type, and experience, this is effectively identical to creating an entirely new renter with some experience. Furthermore, this also effectively limits the maximum amount of information that any renter can have about the market, as, on average, renters are replaced every $n / R$ stages, where $n$ is the number of renters and $R$ is the number replaced each stage.

## 3 Results

### 3.1 Basic Simulations

All of the simulations in this paper hold constant a number of parameters unless otherwise specified. I have chosen to use a market with eleven renters and eleven landlords with one at each integer reservation price from one to eleven, because the Walrasian equilibrium price and quantity of such a market are, conveniently, each six, and the total market surplus is 30 . As indicated above, agents' information is updated only at certain intervals rather than continuously. Because the information each agent possesses is only updated at the end

| Average Price | Total Surplus | Renter Surplus | Landlord Surplus | Transaction Ct. |
| :---: | :---: | :---: | :---: | :---: |
| 6.0003 | 26.9483 | 13.474 | 13.474 | 6.3861 |

Table 1: Basic Simulation Results
of each stage, each iteration of the market within a particular stage has identical starting parameters. In order to obtain results that are representative of the average outcome of the market, each stage consists of the same market run being played out 30,000 times with the results averaged before information is updated. ${ }^{8}$

The most basic kind of simulation exercise I perform contains only two stages: the bootstrap stage (where agents gain information), and a single trading stage producing 'results' for analysis. Table 1 shows the results of a typical simulation of this type for the first post-bootstrap stage.

The Walrasian equilibrium for this market would be six trades at a price of six, with a total surplus of 30 divided evenly between renters and landlords. As can be seen from Table 1, while the average trade price is almost exactly six, a surplus of 30 is not nearly realized-the total surplus is in fact more than $10 \%$ less. This loss is divided evenly over the renters and landlords, and caused by a number of agents getting to trade who would not ordinarily get to trade in the Walrasian equilibrium.

Table 2 shows the overall surplus expectations for each of the renters and landlords before the bootstrap, after the bootstrap, and after the first stage. Each agent comes into the bootstrap with no expectations at all: that is to say, with the expectation that the

[^7]| Renter | Pre-Boot | Bootstrap | 1stStage | Landlord | Pre-Boot | Bootstrap | 1stStage |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 1 | 0 | 0 | 0 | 1 | 0 | 1.4586 | 1.5502 |
| 2 | 0 | 0.0534 | 0.0415 | 2 | 0 | 1.2884 | 1.3805 |
| 3 | 0 | 0.1371 | 0.1084 | 3 | 0 | 1.1226 | 1.2087 |
| 4 | 0 | 0.2496 | 0.2147 | 4 | 0 | 0.9428 | 1.0069 |
| 5 | 0 | 0.3955 | 0.3659 | 5 | 0 | 0.7551 | 0.7815 |
| 6 | 0 | 0.5691 | 0.5597 | 6 | 0 | 0.5658 | 0.5574 |
| 7 | 0 | 0.7566 | 0.7830 | 7 | 0 | 0.3972 | 0.3675 |
| 8 | 0 | 0.9433 | 1.0066 | 8 | 0 | 0.2512 | 0.2162 |
| 9 | 0 | 1.1225 | 1.2090 | 9 | 0 | 0.1370 | 0.1083 |
| 10 | 0 | 1.2940 | 1.3865 | 10 | 0 | 0.0532 | 0.0412 |
| 11 | 0 | 1.4537 | 1.5452 | 11 | 0 | 0 | 0 |

Table 2: Renters' and Landlords' Expectations
alternative to accepting a feasible trade (at any transaction count) is to receive no surplus at all. Though they gain great deal of experience during the 30,000-iteration bootstrap stage, agents have far from what might be considered 'perfect' information in the first postbootstrap stage. For instance, Renter 11 would expect a surplus of 5 in a Walrasian market, but after the bootstrap, that renter has an expectation of $1.45 .{ }^{9}$ This is hardly surprising because of the way in which bargaining is done: in the bootstrap, Renter 11 would trade with literally anyone, gaining a surplus of 0 from trading with Landlord 11, a surplus of .5 from Landlord 10, and so on, gaining a surplus of five only from trades with Landlord 1. As one would expect, information is symmetric between the renters and the landlords; for instance, Renter 1 and Landlord 11 are positioned to get equal amounts of surplus from this market and have almost exactly the same expectations.

In the first stage after the bootstrap, both the renters and the landlords gain additional information. Those traders who get to trade increase their expectations, and those for whom

[^8]trading is a rarity scale back what they expect, ${ }^{10}$ but again, information between the renters and the landlords is almost perfectly symmetric.

### 3.2 Fifty Stage Simulations

A two-stage simulation exercise, however, does not tell us anything about how the market evolves as agents gain more information. In order to see what happens as both sides gather information at about the same rate, simulations were run out to 50 stages (49 stages after the bootstrap). Table 3 shows the averaged results of 30 such 50 stage simulation runs, where each stage was comprised of 30,000 iterations. ${ }^{11}$

Over the course of 48 additional stages, both the renters and the landlords gain a great deal of information. By the end of the last stage, total surplus reaches just over 29, or about $97 \%$ of the Walrasian equilibrium, and is still split evenly between renters and landlords. The average trade price is almost exactly six and the total number of transactions has fallen to 5.8.a reflection of the fact that there are many fewer extramarginal trades and that the last trade (between Renter and Landlord 6, at a price of six, for no total surplus) does not always happen. Figure 1 shows total surplus over these stages.

It is important to note here that even after 50 stages of 30,000 market runs apiece, the market is still a fair distance from the Walrasian equilibrium-a deadweight loss of $3 \%$ in fact.

[^9]| Stage | Trade Price | Total Surplus | Renter Surplus | Landlord Surplus | Transaction Ct. |
| :---: | :---: | :---: | :---: | :---: | :---: |
| B | 6.000 | 20.008 | 10.004 | 10.004 | 7.941 |
| 1 | 5.999 | 26.965 | 13.486 | 13.478 | 6.386 |
| 2 | 6.000 | 27.203 | 13.605 | 13.597 | 6.303 |
| 3 | 5.999 | 27.299 | 13.652 | 13.648 | 6.289 |

Table 3: Summary Statistics for a 50 Stage Simulation

Total Surplus vs. Stage

Figure 1: Total Surplus by Stage

Much longer runs under similar conditions (1,000 stages), show an increase in Total Surplus of only .3 over the 50 stage runs, making it unclear as to whether or not this is, in fact, asymptotic convergence to the Walrasian equilibrium. On the other hand, even information that is far from perfect can create results fairly close to the Walrasian outcome.

Table 4 shows the average expectations for renters and landlords after the first and 49th stages. Again, there are large changes in the manner we would expect: those agents who should not get to trade in a Walrasian world have their expectations decreased, while those who can reliably expect to trade (renters with high reservation prices and landlords with low reservation prices) see their expectations increase. ${ }^{12}$

Table 4: Agents' Expectations for a 50 Stage Simulation

Expectations for each agent are not limited to a single number, but rather contain a data point for each possible transaction count in the market. For example, in a market with 11 renters and 11 landlords, each agent would have 11 different expectations, telling that agent how well he/she can expect to do if he/she rejects a trade at each transaction count. Table 5 shows the full expectations for the renters and for the landlords in the first post-bootstrap stage and the 49th. For those agents who always get to trade, expectations fall as the transaction count increases, but increase across the board from the first to the 49th stage. Likewise, for those agents who very rarely get to trade, expectations either fall or stay the same (because these agents never reject a trade).

Expectations are more interesting for agents at the margin, however. For Renter 5 and Landlord 7 (who should never get to trade in the Walrasian equilibrium, but who, as we will see, get to trade about half the time even late in the late stages of the simulation runs), expectations initially decrease as the transaction count increases (the best deals are most those agents simply never get the chance to reject a trade anymore.

Table 6: Realizations for Renters and Landlords by Reservation Price
likely to leave the market early), but these expectations shoot back up when the transaction count rises over the expected number of trades. In order for the market to even reach such a high transaction count, an unusual trade must have happened earlier in the market run, leaving available at least one agent who would normally trade in a Walrasian setting. As all of those agents have strictly downward-sloping expectation curves, these agents seem more and more 'desperate' as the transaction count increases, thus increasing both the probability of trading, and the return from doing so for Renter 5 and Landlord 7.

Table 6 shows the average surplus each renter and landlord earned in the first stage after the bootstrap, as well as the 49th. As we would expect, the renters willing to pay more and the landlords willing to sell for less get more total surplus, though the difference in surplus between agents that actually trade is about half the difference in their reservation prices. Again, there exists almost a perfect symmetry between the high reservation price renters and their corresponding low reservation price landlords.

### 3.3 Two-Replacement

To get a very basic look at the effects of asymmetric information, I began by simply replacing a fraction of the renters with more naive counterparts of identical reservation price at the end of each update period. This is essentially the same as a natural churning in the market, where some renters leave for other places and new, less experienced renters take their places. As it seems intuitive that everyone has at least some knowledge of the market, the starting knowledge for the replacement agents comes from the beginning of the stage after the bootstrap, rather than from before the bootstrap.

Table 7 shows the results from randomly replacing two of the eleven renters each stage. As we would expect, landlords begin to do significantly better than renters and landlords' expectations continue to rise. The number of transactions moves quickly up above the Walrasian equilibrium, increasing to about $5 \%$ over the same stage of a no-replacement simulation. Overall, the total surplus drops about $5 \%$; though the landlords are about $3 \%$ better off than they were before, the renters are only getting about $85 \%$ as much surplus.

An interesting effect of this replacement is to bring high reservation price landlords back into the market at least some of the time. When a high reservation price renter is replaced with a more naive counterpart, it may suddenly be possible for one of the landlords with a cost over six to do a deal, increasing the average number of trades in that stage.

One of the problems with this particular data set is that the market outcome does not converge, but rather bounces around somewhat erratically, even at late stages. This is hardly surprising, because at every stage I continue to introduce random elements by way of replacing two of the renters with less experienced counterparts. In order to see if there is

| Stage | Trade Price | Total Surplus | Renter Surplus | Landlord Surplus | Transaction Count |

Table 8: Regression Statistics
a correlation between the renters replaced and the outcome of the next stage, I estimated a simple linear regression of the renters' surplus versus the highest reservation price of a renter replaced in the previous stage, predicting that the relationship would look like Equation 2. Figure 1 shows the results of this regression.

$$
\begin{equation*}
B=a R^{t-1}+b \tag{2}
\end{equation*}
$$

$B=$ The surplus for renters at time $t$
$\mathrm{R}=$ The highest RP of a renter replaced in stage $\mathrm{t}-1$

This yields a coefficient for the dependent variable of -.0894 with a standard deviation of 0.021 , a result that is statistically significant well past the $95 \%$ confidence interval. This regression explains almost $40 \%$ of the total variation, which suggests that the total surplus received by renters is very highly correlated with which renters have been recently replaced. The relationship is very likely affected by not only one but both of the renters replaced and

Figure 2: Renter Surplus vs. Highest RP Renter Replaced at t-1
is exponential in shape, meaning that the replacement in previous stages is also a factor. Nevertheless, this basic regression seems sufficient to show that while there may be some kind of 'average' stage in the long term, any actual stage will deviate from that based upon which renters have recently been replaced.

In order to find such an average, two possibilities suggest themselves: either increase the number of renters and landlords in the market so that a single replacement does not affect all of the renters of one reservation price, or average together multiple simulations with the same starting parameters. Both options seem equally valid, but the second approach was chosen because it was comparatively easier to work with a smaller number of agents and average the results afterwards. Table 9 shows the results of 30 such simulation runs averaged together. Most of the uncertainty disappears and the correlation with the identities of the agents who

Figure 3:
were replaced disappears entirely.

Figures 3-7 show the effect of different levels of churning on the outcome of the market. As we would expect, a greater level of replacement on the renter's side (and henceforth less experience for the average renter) leads to a higher average price, lower surplus for the renters, higher surplus for the landlords, and an overall loss of total surplus-almost an $8 \%$ drop from the Walrasian case, and a $7 \%$ drop from the no-replacement case. One interesting effect of replacement is that the average number of transactions steadily increases with the amount of replacement, a trend caused by an increasing willingness on the part of renters to take all kinds of deals that they would reject with better information.

Another interesting effect of replacement is that over the first 15 stages of trading, landlord surplus actually rises more slowly with some replacement than it does in the no-

| Stage | Trade Price | Total Surplus | Renter Surplus | Landlord Surplus | Transaction Count |

Table 9: Summary of 30 Two-Replacement Simulations

Seller Surplus vs. Stage

Figure 4:

Total Surplus vs. Stage

Figure 5:

Trade Price vs. Stage

Figure 6:

Transaction Count vs. Stage

Figure 7:
replacement case, despite the fact that the amount of surplus that landlords receive is actually greater in later stages. Some level of replacement among the renters clearly creates confusion for the landlords. This is because at least one trade in ten is with a renter who has only bootstrap stage expectations.

Tables 10 and 11 show the expectations after the 50th stage for both renters and landlords in 2, 6 , and 11-replacement markets. Much like with the overall surplus, we can see that a majority of the effect of replacement on the renters happens as soon as any replacement is begun. ${ }^{13}$ Even with just two renters per stage replaced, expectations for those renters with high reservation prices drop by $25 \%$ or more. Near the margins, however, where renters only sometimes (or only rarely) get to trade, expectations do not change very much. Part of this is no doubt due to the fact that it is more difficult to take advantage of someone when a trade is only barely possible in the first place, but a great deal of it is due to the way in which the landlords. expectations change.

As we can see from Table 11, those landlords who always get to trade do indeed come to expect a small bit more surplus-Landlord 1 expects almost three\% more at the beginning of the 11 replacement scenario compared to the 0 replacement one. Nevertheless, compared to differences in the distribution of surplus between renters and landlords, this is tiny. For landlords closer to the margin, however, this is not the case at all. At transaction count one, Landlord 6 expects more than $30 \%$ more surplus in the two renter-replacement case than the zero-replacement case, a figure that rises to over $40 \%$ in the 11 replacement case. Table 11: Landlords' Expectations in Different Replacement Simulations
low transaction counts, Landlords 7, 8, and even 9 see large percentage increases in their expectations. This makes a great deal of sense, because the replacement sometimes puts their naive high reservation price renters into the market.easy targets even for high reservation price landlords. An interesting effect of this is that it effectively increases the competition for the high-end renters, providing downward pressure on the expectations of those landlords with low reservation prices. This effect dwindles as the transaction count increases (the naive renters are likely to exit the market early) but it never entirely fades away. Even with the higher transaction count in the with replacement simulations, however, expectations beyond transaction count 7 tell us very little because the market very rarely gets to such a point after the first few stages.

Another interesting effect of replacement is that landlords with reservation price 3 and above begin to expect less in the with-replacement scenarios than they do in the no-replacement scenarios, while the expectations held by renters with reservation price less than 7 actually go up. Although unexpected and in some ways an artifact of the way in which the model works, this is a very interesting result. As landlords' expectations increase, they can find themselves in a situation late in a market where they simply will not trade, despite possible deals, because they want more than the renters are willing to give up. When this happens, neither side receives any surplus, and because the landlords were the ones unwilling to compromise, they get a zero averaged into their expectations, dropping these expectations radically and making the landlords take very weak bargaining positions late in the market. As the renters who tend to be left near the end of a market learn this, their expectations increase and they actually manage to do slightly better. While in some ways it seems strange for landlords to

Table 12: Distribution of Surplus By Reservation Price
back off far enough to weaken their positions relative to the renters, this does make some sense if one considers that the penalty for not renting a unit at all is to obtain zero surplus.

Table 12 shows the actual distribution of surplus in the $0,2,6$, and 11 replacement cases. Again, those landlords who always get to trade do not fare very much better than they did before, gaining about $5 \%$. The big losers are clearly the high reservation price renters who now take many sub-optimal deals, though again the difference between a small amount of replacement and total replacement is only 5\%. The extra-marginal or nearly extra-marginal landlords are the ones who gain the most, at least in percentage terms, because they had so few (or no) opportunities for trade before but can now expect to run into a relatively naive renter with at least some probability. Finally, while the very low reservation price renters gain not at all because they still never get to trade, the with reservation prices near six actually show some small gains, because, as I discussed above, several landlords are conditioned into taking weak bargaining stances as the transaction count increases.

Table 13 shows the gains by renters divided by their reservation price. If we take reser-

Table 13: Difference in Renter's Surplus Divided by Reservation Price
vation price as a reasonable proxy for income, an assumption that seems reasonable because people tend to spend about one-third of their income on housing, then it gives us an idea of how replacement affects renters proportional to their income.

### 3.4 Implications of Replacement

As the Walrasian outcome has the same price and quantity as the competitive outcome, my comparison of markets with replacement to those without is essentially a comparison of the deviation of markets with asymmetric information from the competitive equilibrium.

The effect of this asymmetry in a market is, with one exception, strikingly similar to the effect of monopolistic behavior. As replacement increases, renter surplus falls, landlord surplus increases, the average trade price rises, and total surplus falls (as what the landlords gain does not quite make up for what the renters lose). In a classical monopoly, we would expect these effects to be more exaggerated than they are in my market, but increased replacement clearly takes us a long way in this direction. One big difference between my
market and one dominated by a monopoly, however, is that the number of trades actually increases as the number of replacements goes up. With a greater number of replacements, it is increasingly likely that in any given stage, the high reservation price renters have been replaced; it therefore becomes easier for high reservation price landlords to edge in and make trades. If even one such trade happens early on in a market iteration as the market plays out, it becomes increasingly clear to the remaining landlords that such a trade must have occurred, and these landlords lower expectations at high transaction counts allow renters who might otherwise not have gotten to trade to do so, increasing the number of trades.

Even with a great deal of replacement, however, renters are still much better off than they would be facing a perfectly price-discriminating monopolist, in which case we would still expect a total of six trades, but with the entire surplus of 30 going to the landlord.

### 3.5 Extramarginal Trading

With reductions in the amount of replacement, the market moves closer to the Walrasian outcome, and the number of trades involving at least one extramarginal agent falls, eventually reaching about $10 \%$ when there is no turnover in the market. With some replacement, however, the extent of extramarginal trading rises substantially, just a single renter out of eleven every stage results in a $60 \%$ jump in the proportion of trades that are extramarginal to about $16 \%$. This result seems quite intuitive; after all, the less knowledge renters have, the more likely they are to take trades that would, with better information, appear suboptimal. Even so, the size of this increase is not as large as one might expect. With one replacement per stage, a renter gets, on average, about 10 stages of experience before being removed from

Figure 8: Percentage of Trades in a Stage that are Extramarginal
the market, so the average renter in a market has about 5 stages of experience. In a situation where all agents have only 5 stages of experience, however, such as the no-replacement market after 5 stages, the number of extramarginal trades is over $23 \%$. Again, this is a direct result of the ability of high reservation price landlords to get lucky and edge into the market.

### 3.6 Decomposition

Even from all of this, it the question remains as to what leads to the changes: is it increased expectations on the part of landlords, decreased expectations on the part of renters, or some of both? A unique way of testing this is available because of the modeling approach I have adopted: renters used to one kind of market can be paired against landlords used to another kind of market and the results observed.

| Type | Av. Price | Total Surplus | Renter Surplus | Landlord Surplus | Transaction Ct. |
| :---: | :---: | :---: | :---: | :---: | :---: |
| No-replacement | 5.999 | 29.076 | 14.540 | 14.536 | 5.820 |
| Replacement | 6.240 | 28.844 | 13.454 | 15.390 | 5.891 |
| Decomposition | 5.990 | 29.313 | 14.659 | 14.653 | 5.843 |

Table 14: No-Replacement Renters and Replacement Landlords

| Type | Av. Price | Total Surplus | Renter Surplus | Landlord Surplus | Transaction Ct. |
| :---: | :---: | :---: | :---: | :---: | :---: |
| No-replacement | 5.999 | 29.076 | 14.540 | 14.536 | 5.820 |
| Replacement | 6.240 | 28.844 | 13.454 | 15.390 | 5.891 |
| Decomposition | 6.343 | 27.971 | 12.634 | 15.338 | 5.852 |

Table 15: Replacement Renters and No-Replacement Landlords

Table 14 shows the result of running such a simulation with the usual parameters and no replacement, but beginning with renters who already have 50 stages of experience in a market with no replacement matched with landlords who already have 50 stages of experience in a market with two out of eleven renters replaced each stage. ${ }^{14}$

As we can see, increased expectations alone provide no benefit to the landlords, as they experience no gain in surplus when compared to landlords in the 50 th stage of a simple no-replacement scenario. The average number of trades is ever so slightly higher than it was before, due mostly to more trading by renter and Landlord 6.

Table 15 shows the opposite experiment from the one described above, using landlords with experience in a no-replacement market and renters who have experience in a market with two out of eleven renters replaced each stage.

[^12]Here, the effect is huge. Even without the increased expectations on the part of the landlords, the renters do almost as badly as they were doing against landlords who had learned to take advantage of them. This decomposition is interesting because it shows that in a Nash-bargaining environment like this, an agent basically has to agree to be taken advantage of in order to get less than he/she should expect. Even if all of the landlords increase their demands, hard bargaining by the renters can keep the distribution of surplus even.

### 3.7 Speed of Convergence

In grounding this kind of simulation in the real world, an issue that I have not yet considered is the speed at which agents learn compared to actual renters or landlords. After all, most of my simulations consist of 50 stages, each of which consists of 30,000 iterations: a number of 'experiences' much larger than any actual person ever actually accrues.

Because agents in my simulation can only learn through their own experience, that is, their knowledge can only come from market simulations, an additional number of experiences is needed simply to compensate for the fact that actual renters or landlords have additional sources of information available to them. For instance, an actual renter can learn a great deal about what is currently available simply by looking at the daily classifieds or by taking a couple of hours to view a selection of different units, and many renters inquire with friends about their experiences (as, perhaps, do landlords).

Another factor making the numbers involved less significant is the limit to how much can be learned about a market during any particular stage. Because agents update their
expectations between stages, the market will not be exactly the same during any given stage as it was during the previous stage, and as a result, the optimal strategy for an agent actually changes as the market evolves. This kind of social learning limits the amount of information that any agent can collect in a given stage, regardless of how many iterations are run.

Nevertheless, in order to make sure that my results are not overly sensitive to changes in the number of iterations or the number of stages, I ran several simulations with a different number of iterations at each stage, as represented in Figure 9. Even between the simulations with 10,000 and 100,000 iterations a stage, there is virtually no difference in the rate at which agents learn (judged by the total amount of surplus gained at each stage in the market).

Stage vs. Total Surplus

Figure 9: Total Surplus by Stage

Figure 10 shows the same graph with the addition of a simulation using just 10 iterations per stage. With so few experiences, however, agents learn very little and even a couple
of unusual iterations are enough to cause large swings in the total surplus. As a result, while total surplus is still generally moving higher, the result of any particular stage is very unpredictable.

Stage vs. Total Surplus

Figure 10: Total Surplus by Stage

From this we can relatively reasonably conclude that while agents are clearly learning as much as is possible from each stage, my particular choice for the number of iterations is not badly biasing the outcome. One might argue that, if we equate a stage with a year, this pace of learning seems unrealistically fast. On the other hand, 5 stages of learning without replacement is sufficient only to get within about $90 \%$ of the Walrasian outcome: a figure that seems a little low if anything.

If we indeed wish to somehow equate stages with years, then one might argue that the

50 th stage is the wrong one to analyze because no actual market ever gets there. ${ }^{15}$ Because of the fact that there are inevitably changes in the national economy and other factors exogenous to the market that nevertheless have important consequences for its outcome, we should perhaps instead analyze these markets after only the first few stages. Figure 11 shows the total surplus versus stage graph from earlier, but out to only five stages.

Total Surplus vs. Stage

Figure 11: Total Surplus by Stage

While, after 5 stages, none of the markets are as close to the Walrasian outcome as they are after 50 stages, the fundamental analysis does not change very much. Even in the early stages, renters in a replacement simulation suffer significant losses compared to their counterparts in a no-replacement scenario, losses that are not made up for in gains by the

[^13]landlords. Total surplus in the 5th stage is $3 \%$ lower in the one-replacement case than in the no-replacement case, and is $5 \%$ lower in the eleven-replacement case. Even after the 5 th stage, these markets show significant deadweight loss.

## 4 Conclusion

In this paper I have used agent-based modeling to explore the impact of asymmetric information upon housing markets. My most significant findings are twofold. First, in real-world terms, the impact of asymmetric information looks a great deal like the distortion caused by monopolistic influence: the greater the renter-replacement rate in a market, the greater the deadweight loss and the greater the imbalance between the amount of surplus received by renters and amount received by landlords. One important difference, however, is that the loss is almost exclusively suffered by the renters with the highest reservation prices; because of the increased extramarginal trading that occurs with renter-replacement, those renters with reservation prices just above or below the Walrasian market-clearing price actually manage to do better with replacement than they do without it.

Second, the magnitude of the difference between the perfectly competitive outcome and my results suggests strongly that Gale's [4] results are not robust to even relatively modest changes in his assumptions. Comparing his third model (which includes bounded rationality) to my model, for instance, the only differences are that my model contains a slightly more rational learning model and that it lacks a profit-maximizing auctioneer, changes that intuitively seem to make the model more realistic. While this does not at all detract from
the analytical beauty of Gale's results, it does suggest that very few actual markets are likely to have outcomes near the Walrasian equilibrium.

There are a number of other very interesting results to come out of my analysis. First, that market turnover (and therefore the possibility of very naive high reservation-price renters) allows extramarginal landlords to edge back into the market, thereby limiting the gains of low reservation-price landlords. Second, that in a bargaining environment like the one I chose, participants can only be taken advantage of when they lack knowledge about the market: landlords with very aggressive bargaining positions fared no better than those who simply expected the Walrasian outcome when paired with renters who had good information.

There are a number of promising avenues for applications of agent-based modeling to the problem of how market equilibria are affected by asymmetric information. The most immediately interesting would be a slight change to my replacement mechanism so that only those renters who are actually managing to participate in the trading are replaced. As it is, in some stages of the replacement simulations, only very low reservation-price renters end up being replaced, effectively meaning that no replacement happens that stage.

This paper has used random replacement in order to study the effects of asymmetric information. However, the ability to replace agents between stages gives us the ability not only to do it randomly and without changing the overall balance of the market, and also to do it according to some feedback mechanism, changing the number or landlords or renters at each reservation price. Effectively, this allows us to create a market that evolves in the manner that real markets do.

In a more general sense, other possibilities for this kind of modeling are practically
unlimited. For instance, incorporating different quality housing units is something that seems both entirely reasonable and also very useful. Social networks are another topic that is very hard to consider analytically but that could be tackled in a relatively straightforward manner by agent-based modeling.

Finally, while I have not pursued it, these results also have implications in labor markets where large companies very likely have the same kind of informational advantage over individual workers and where a large union might have this kind of advantage over many small companies.

My results suggest that even modest departures from the assumption of perfect information yield significant departures from equilibrium outcomes. The ability to not only quantify the extent of these deviations but also to examine the process by which they come to be and the distributional impacts on each agent is an indication of the power of this agent-based approach. In our attempt to understand how prices and market outcomes are generated, this represents a significant step forward not only because it shows just how important it is to relax the assumption of perfect information, but also because it demonstrates the power of this kind of modeling to help us do so.

## Acknowledgments

I would like to thank professors Ralph Bradburd and Steven Sheppard for their invaluable help: they both made an incredible amount of time throughout the year to help me and I never could have come this far without them. I would also like to thank professor Al Roth
from Harvard for taking the time out of his trip to talk with me about this project and for his very insightful comments: along with many other things, Section 3.7 came almost directly from answering his questions.

## Appendix I: Glossary

Agent-A participant in a market: in this model specifically, a renter or a landlord.
Bootstrap Stage-A special kind of stage designed to give initial information to agents. Because totally naive agents would accept any deal presented to them, I randomly reject half of the proposed trades in this stage in order to give them information about what kind of surplus they can expect if they reject a feasible bargain at any point.

Expectation-An agent's belief about how much surplus he/she can expect to receive after rejecting a feasible bargain. A separate such belief is kept for each possible value of the transaction count.

Extramarginal-An agent that would not have gotten to trade in a Walrasian outcome. Alternatively, any trade involving such an agent.

Iteration-A single market simulation, continued until no more trades are possible, or until some predefined number of possible successive trades have been unsuccessful.

Stage-A series of market simulations, between which agents do not update their expectations. This typically consists of 30,000 iterations.

Transaction Count-In any given market, the number of deals that have already been made. As there is no other way to mark the passage of time in my model, agents keep a separate expectation for each possible value so as to be able to differentiate based on the progress of the market.

Table 13: Extramarginal Trades By Replacement \# and Stage

[^0]:    *This work submitted in fulfillment of the requirements for a degree with honors at Williams College, Spring 2004

[^1]:    ${ }^{1}$ For convenience, I assume that the last trade, between a renter of reservation price six and a landlord of reservation price six, happens.

[^2]:    ${ }^{2}$ A discussion of the particulars of these assumptions as well as their relation to my own model can be found at the end of Section 3.

[^3]:    ${ }^{3}$ Increasing this number has relatively little effect on the amount of information agents acquire, as there is only so much that can be learned from a market in which every agent is taking any deal that nets positive surplus.

[^4]:    ${ }^{4}$ Much of this section describing the bargaining model is based upon a working paper by Bradburd and Sheppard.

[^5]:    ${ }^{5}$ Even in the market for single-family homes, very few such units are sold between Thanksgiving and the middle of January, creating an effect much like the closing of a market, even though the opportunity for surplus is not permanently lost.

[^6]:    ${ }^{6}$ Previous experiments by Bradburd and Sheppard have found that moving this number

[^7]:    ${ }^{8}$ Section 2.5 talks about the necessity of such averaging, and Section 3.7 gives some insights as to what happens without it.

[^8]:    ${ }^{9}$ Expectations are used to calculate the disagreement point, so, in the next stage, the worst trade that this renter will accept is one that nets a surplus of at least 1.45

[^9]:    ${ }^{10}$ Those agents who have expectations that are too high end up rejecting viable trades and either end up with less later on or, in some instances, do not get to trade at all, which results in their having a zero averaged in.
    ${ }^{11}$ Whereas with the two stage run where averaging was not strictly necessary (because every run was within a very small distance from the average), it became much more important to average the longer runs. Here, each stage affects the one afterwards, meaning that in a single run, one stage with atypical results could profoundly affect several stages thereafter.

[^10]:    ${ }^{12}$ Expectations only change when an agent actually rejects a deal, however, so for those agents who find themselves pushed out of the market, their continued demand for some surplus is a remnant of very early good fortune that has never been wiped out, because

[^11]:    ${ }^{13}$ Again, this is unsurprising because in the no-replacement scenario, renters have 50 stages of experience, whereas in the one replacement scenario, they have an average of just over five stages of experience.

[^12]:    ${ }^{14}$ In this case, because the renters and landlords both already have experience, it is not necessary (nor desirable) to run a bootstrap stage. In both this and the next simulation, the expectations fed in were the result of averaging the final expectations for the appropriate agents from 30 different simulations run out to 50 stages. Without such averaging, the results of one of the decomposition simulations would have been heavily dependent on which renters happened to be replaced in the last stage of the first simulation.

[^13]:    ${ }^{15}$ It does not seem clear that a one-to-one correlation is the only possible choice here, but it serves to illustrate the point and the argument would work much the same with a two-to-one or a three-to-one correlation.
